Come to think of it.
Coherent photons at HF would make a remarkable (laser like?) antenna
pattern.

Thanks! That does help me understand the effect much better. I was hung up on the electrons jumping between the shells (s, p etc.) and I was having problems with that because it dawned on me that the energy levels for the tight binding electrons are associated with very specific quantum energies, depending on the type of atom, so how could we produce any desired frequency that we wanted? I considered that simultaneous "jumps" of multiple electrons could produce quantum energies for any frequency we wanted but that is too complicated and it is much more easily explained by your free electron concept.

Nice. So you don't really want to refer to the FSU page at all. Why bring it up? The topic was about free space interference and had nothing to do with match points.

Same ol' Cecil; try to sneak in some irrelevancy and then get agitated when you are called on it.

Hi Steve,

Welcome to HF! I'm guessing your power supply is the RS-20, the same as mine. It has a *peak* current capability of 20A. In continuous duty, it's rated at 16A: http://www.astroncorp.com/linear.shtml. My old Kenwood TS120S transceiver (approximately equivalent in terms of maximum current demand) will dim the pilot lamps on hard voice peaks and keydown CW at 100W output. I like Frank's idea as an interim solution, though a heftier supply is a better long-term solution.

73,
Bryan WA7PRC

One super simple antenna can be built using a BC to SO-239
adapter. Stick a 1/4 wave length of thick wire or rod that will fit
snug into the SO 239 end hole of the adapter. Screw onto radio.
Presto! Instant antenna. You can change bands too if you change
the rod or wire to another one of different length.

I run an RS-20 paralleled with a deep discharge
marine battery. I not only run my IC-756PRO from
that configuration but I run my SG-500 amp at
the same time - never had any problems.

In the 1980's, Bruce Brown W6TWW came up with a similiar scheme for 2M using thick copper wire in a BNC connector. Half way up the rod, the wire was shaped into a coil. On top of the wire was a copper circular plate for a top hat. The antenna was compact, worked well, and of course was an eye-catcher. Maybe some gurus can model it for dimensions and you can try it out.

Don't worry about it... If the power supply doesn't handle the peak current, you can always add a parallel battery. Even a small 7MAH (motorcycle size) would help.

I've got an 957 (before D, but with the DSP option) in my truck and it's provided very faithful service despite the typical voltage variations of a vehicle. Yaesu doesn't recommend running it below 12.0 volts, and there used to be warnings from newsgroups and such that it could lose the factory settings if you try to run it below that, but I've seen dips as low as 10.5 volts with the radio on while cranking the motor to start the truck, and never lost the settings. Just in case, I'd google the three button "secret" menu that shows the factory settings and write them down (Can't recall, but it's something like hold down abc while pressing the on button.). I've got them somewhere, but it's been so long I doubt I could find them, and I've not had a problem anyway. The rig gets great reports and does fine, even on a pickup truck with either an ATAS-120 or Ironhorse hamstick antennas... It's a great choice of radio, versatile and sturdy. The worst issue is mounting the head where I can reach it without stretching while I drive, but that won't be an issue for you if you're going to use it at your QTH. It certainly doesn't have some of the choices and options of a big rig like an Icom 756Pro2, but doesn't cost that much either... Because it is a small rig, you will need to bet used to selecting various menus, but most of your operating will likely center on three or four, at most, with only rare use of the others (except for fine adjustments for maximum power

out of a linear, who ever changes the power output, for example? I know the one in my truck has only been below 100 watts when someone once bet me I couldn't get across the state on less power, and that was sitting still. Running mobile, you want something you can operate without looking, and the 857 has fit the bill there very well.

Astron supplies are pretty hefty, compared to a lot of them, and it should do just fine in normal service. On the other hand, if you intend to run high duty-cycle rtty or similar, get the bigger supply or add a battery in parallel right away. For voice (ssb) or CW, you shouldn't have much of a problem, if my experience with the 857 is any indication.

Good Luck and 73.

Hello Roy...

The definition of a committee is a dark alley down which you lead ideas
so that you can strangle them. My impression is that the QST editorial
process is riddled with committees, and they're quite effective (hi).

I've given up writing for them due to the many problems you recounted -
I don't say forever, but for the time being. I'm very tired of
objections that don't make any real sense, while seeing this kind of
article (which also makes no real sense) published as is.

QST used to be a respected technical journal. It's grown inbred,
inflexible, inaccurate and inconsistent. It no longer really serves the
amateur community - it seems to largely serve itself.

Maybe a (metaphorical) bomb will go off or someone will start a
revolution and it'll change. Not likely, but maybe.

Perhaps a group of (former) writers could prepare a joint "declaration
of limited support" to present directly to the ARRL brass (bypassing the
editors) to call for action/changes.

Nice to run into you here.

Best regards - Robert Victor VA2ERY

OK Roy you lost me.

I'll confess that I'm one of those new no code guys that concentrated on the answer pool for three months in order to get an Extra Class license. What I'm trying to do now is relearn enough electronics to become a competent communicator for EMCOM purposes. You see back when I was last in radio your transmitter would keep you warm and provide enough light to read the manual by. Now it is thirty years since my Novice license expired and not only are the newer radios all solid state they do most of their signal processing digitally. By my point of view that only makes me as yet not fully trained rather than the devils personal representative in amateur radio.

Are you being serious when you say that much of the difference in the mobile rigs performance may be the vehicle on which it and therefore it's antenna are mounted? IS the body of my half ton cargo van doing a substantial amount of the job of radiating my signal? If I mounted the same antenna with the same mount on my Saturn should I see a difference on a field strength meter that is the same distance to the centimeter from the antenna over the same parking lot with the antenna over exactly the same spot?

I hope we can agree that EM waves do not have
the ability to decide to do anything - that they
must obey the laws of physics, some of which humans
may have not yet discovered.

One of the requirements of wave cancellation is
collimation and it happens automatically within
a coaxial transmission line. A laser beam is
also relatively easy to collimate. Because of
that, it makes a good example source for a
1/4WL thin-film anti-reflective coating.

at eBay: http://cgi.ebay.co.uk/ws/eBayISAPI.dll?ViewItem&item=320177560839

Check bellow what you are getting for one
price!!!

Kenwood TS-450SAT Review at eHam : http://www.eham.net/reviews/detail/989
Lovely Kenwood. Superb condition. Tunes any antenna. Covering 160 through 10 meters including the WARC bands with 100 watts output. From Non-smoking environment.
---> with YK-88C1 CW Filter 500 Hz [8.83 MHz IF !!!
---> Power Cord
---> Instruction, external control & Service manual's!!!

Kenwood MC-60 desk mic Review at eHam :
http://www.eham.net/reviews/detail/1112
The Kenwood MC-60A has been a popular desk mic among Kenwood owners for many years. It has a communication type dynamic unidirectional moving coil type mic element. It features UP-DOWN tuning plus a built-in pre-amp. There is a switch for PTT (push to talk) and also a lock feature. The mic impedance may be set for 50K ohms or 500 ohms. The frequency response is 150 Hz to 10 kHz (-6dB) with the Preamp off and 200 Hz to 7 kHz (-6 dB) with the Preamp on. The heavy zinc die-cast base provides extra stability. The mic terminates to a standard 8 pin mic plug. The preamp requires two AA cells which are mounted through the bottom of the base.

VHF Alinco DJ 190 Review at eHam : http://www.eham.net/reviews/detail/3076
Alinco DJ-191 Hand-Held 2m Transceiver with extra battery and antenna. Fully working condition!!!

DL4YHF Pic Keyer with memory!!! More info at:
http://freenet-homepage.de/dl4yhf/pic_key.html
Record & Play up to 2 cw messages. The Speed range from 20 to 300 letters per minute. With full manual and schematic.

Roy
For the sake of my continuing education what would I need in terms of
minimum equipment to make a meaningful comparison between antennas?
Just to keep it simple I'm working on two meters and seventy five
centimeters so far in my EMCOM prep work.

Fortunately, antennas still operate the same way they did back when rectifiers glowed blue. In fact, the same as they did when you had to poke a catwhisker around your rectifier.

> the same spot?

Yes.

Declaring a vehicle to be "ground" doesn't give it magic properties. It's a conductor, just like the antenna. Exactly the same current that flows upward on your antenna flows downward along your vehicle. The vehicle and "antenna" comprise an asymmetrical dipole, and neither half is inherently more or less important than the other.

But during wave cancellation, as described by the Melles-Groit
and FSU web pages, the conservation of energy principle leaves
them no choice but that their energy be redistributed in a
different direction toward which constructive interference
can occur.

www.mellesgriot.com/products/optics/oc_2_1.htm

"Clearly, if the wavelength of the incident light and the thickness
of the film are such that a phase difference exists between reflections
of p, then reflected wavefronts interfere destructively, and overall
reflected intensity is a minimum. If the two reflections are of equal
amplitude, then this amplitude (and hence intensity) minimum will be
zero." (Referring to 1/4 wavelength thin films.)

"In the absence of absorption or scatter, the principle of conservation
of energy indicates all 'lost' reflected intensity will appear as
enhanced intensity in the transmitted beam."

micro.magnet.fsu.edu/primer/java/scienceopticsu/interference/waveinteractions/index.html

"... when two waves of equal amplitude and wavelength that are
180-degrees ... out of phase with each other meet, they are not actually
annihilated, ... All of the photon energy present in these waves must
somehow be recovered or redistributed in a new direction, according to
the law of energy conservation ... Instead, upon meeting, the photons
are redistributed to regions that permit constructive interference, so
the effect should be considered as a redistribution of light waves and
photon energy rather than the spontaneous construction or destruction of
light."

Roy is certainly right! The vehicle is the other half of the "dipole". It is why if you stick a bugcatcher at random on a broomstick, it won't work: SWR will be thru the roof.. Or you could hang a dipole for a given band (your choice), then snip off the side that went to the coax shield (or vice versa). So, yes, the vehicle is the other half of the antenna. You could even look at it as an right-side up "L"! :)

You have to look at where the currents go. If you had a completely symmetrical vehicle and put the antenna at the very center of the top, the horizontal currents along the top would produce fields that almost completely cancel, just like a bunch of radials. But when they reach the edge and flow downward, the fields are all in the same direction and add. So it radiates just like a very fat wire.

But if you put an antenna on the edge of the roof, then the fields from the horizontal currents won't cancel and you'll have some radiation from the top as well as the sides. And so forth.

Roy Lewallen, W7EL

That is rather simplistic and not reality reflecting explanation.
Like saying that ground plane, vertical antenna is a dipole.
Vehicle body represents "ground plane" similar to two or more radials. The current flows along the surface of the vehicle, just as along the more elaborate ground plane consisting of more than say 8 radials. Cancellation of current along the body happens, just like in opposite radials in GP.
Radiation pattern is formed between the RADIATOR (whip) and GROUND PLANE (vehicle body).
Additional effect is that vehicle "ground plane" is capacitively coupled to the ground and this is reflected in changes in efficiency depending on the surroundings ground conditions (salty, wet ground, reinforced concrete bridges, etc.)

As far as I understand, dipole refers to dual pole antenna with symmetrical current distribution. Vertical antenna mounted on conducting body of vehicle has current distribution in the "other pole" far from symmetrical. This can be seen in modeling in EZNEC. Try to compare vertical whip mounted on vehicle, with dipole that has one leg horizontal and you will see the difference, far from "nice dipole" antenna.

So as soon as we have more than one radial, and some (horizontal) cancellation is happening it ain't no dipole. It is monopole forming vertical pattern against the ground plane (radials, vehicle body).

That's the way I understand it, without involving photons, Gaussss and other farticles :-)

The energy cannot just disappear by destruction. Photons cannot annihilate
each other; the energy must go somewhere, therefore it must redistribute to
another location. The reference you are looking for is simply stated within
the law of conservation of energy.

It appears that you missed my explanation, so I'll try again.

The currents flowing different directions don't cancel. If they flow in equal amounts, in phase, in opposite directions, then the fields they create nearly cancel. And that's the case along the roof of a car if the car and roof are symmetrical and the antenna is at the center. But it's not the case where it flows vertically along the sides of the car. There, the currents are in the same direction.

> Radiation pattern is formed between the RADIATOR (whip) and GROUND PLANE
> (vehicle body).

The radiation pattern is formed by the sum of all the fields which are created by currents flowing on conductors. The antenna is one such conductor. The body of the car is another.

> Additional effect is that vehicle "ground plane" is capacitively coupled to
> the ground and this is reflected in changes in efficiency depending on the
> surroundings ground conditions (salty, wet ground, reinforced concrete
> bridges, etc.)

That's true. And the coupling of the car body to ground alters the amount of current flowing along the body of the car. This current equals the current flowing into the antenna.

> As far as I understand, dipole refers to dual pole antenna with symmetrical
> current distribution.

Suit yourself. I called the system an "asymmetrical dipole". But like "ground", putting a name on it doesn't change its properties.

> Vertical antenna mounted on conducting body of vehicle

Certainly a whip mounted on a vehicle can be expected to have a
different pattern than a symmetrical dipole, and nothing I've written
has attempted to make a claim that it does. But it sounds like you've
grabbed onto the "asymmetrical dipole" label as a basis for argument. So
please go back over my postings but substitute "Yuri special" for
"asymmetrical dipole" and see if then you find anything I've written
which isn't correct.

Yes. The incident and reflected components of electric field exactly
cancel at the surface of a perfect reflector due to the short-circuit.

I think I know the answer but I need to be sure. The information you
have provided suggest that I should move the antenna from the clip on
mount at the back left corner of the van to through hole mount in the
middle cross bar of my ladder rack in order to get a more omni
directional pattern out of it right? Since the antenna is a fold over
type that I can fold to go under obstructions I think I'll still be all
right if I move it there. I have a traffic directing arrow on the back
cross bar and a full sized strobe beacon on the front cross bar. Are
there any other mobile operation pit falls that anyone would care to
point out?

As a rule, more wire is "said" to be better. Theoretically, you can make a different case but just try transmitting at 160m with a tuner and 80m dipole. At that MF frequency, your tuner will try to reflect so much energy that you will probably hear the crackling and may see a corona, no matter if it is rated at 3KW and your are transmitting at 100W. I have heard of people using tuners to tune their rain gutters and even chain link fences (that worked to some degree at 80 meters). However, I will note that unless you have access to a nearby 8 foot grounding rod to a good moist soil, make sure that the antenna you use is balanced. If you use coax as a transmission line, use a voltage balun with your non-resonant antenna (I would even recommend a voltage balun with a resonant antenna if you must use coax). If your SWR is not too bad, below 6:1 or so, you can make a crude voltage balun by winding 20 turns of coax around a 6 inch PVC pipe and it will function OK for most ham bands. Without the balance or damn good ground, you will make the radio part of your antenna system and may damage it and sustain several RF burns from your microphone.

Guess it's time to re-post a posting I made on this newsgroup on April 9. Here it is:

I'd vowed that I wouldn't hit this tarbaby yet again. But here I go.

Among the junk science being bandied about here is the following supposition:

Suppose you have beams from two identical coherent lasers which, by a system of (presumably partially reflective and partially transmissive) mirrors, are made to shine in exactly the same direction from the same point (which I'll call the "summing point"). Further, suppose that the paths from the two lasers to this summing point differ by an odd number of half wavelengths. So beyond the summing point, where the laser beams exactly overlie each other, there is no beam because the two exactly cancel. Or, in other words, the sum of the two superposed fields is zero. The recurring argument is that because each laser is producing energy and yet there is no net field and therefore no energy in the summed beams, something strange has happened at the summing point (or "virtual short circuit"), and creative explanations are necessary to account for the "missing energy". One such proposed explanation is that the mere meeting of the two beams is the cause of some kind of a reflection of energy, and that each wave somehow detects and interacts with the other.

Well, here's what I think. I think that no one will be able to draw a diagram of such a summing system which doesn't also produce, due solely to the reflection and transmission of the mirrors, a beam or beams containing exactly the amount of energy "missing" from the summed beam. No interaction(*) of the two beams at or beyond the summing point is necessary to account for the "missing" energy -- you'll find it all at other places in the system. Just as you do in a phased antenna array, where the regions of cancelled field are always accompanied by complementary regions of reinforced field. Somewhere, in some bounce from a mirror or pass through it, the beams will end up reinforcing each other is some other direction. My challenge is this: Sketch a system which will produce this summation of out-of-phase beams, showing the reflectivity and transmissivity of each mirror, and showing the beams and their phases going in all directions from the interactions from each mirror. Then show that simple interaction of the beams with the mirrors is insufficient to account for the final distribution of energy.

Next, do the same for a transmission line. Show how two coherent traveling waves can be produced which will propagate together in the

same direction but out of phase with each other, resulting in a net zero field at all points beyond some summing point. But also calculate the field from waves reflected at the summing point and elsewhere in the system due to simple impedance changes. Show that this simple analysis, assuming no interaction between the traveling waves, is insufficient to account for all the energy. A single case will do.

Until someone is able to do this, I'll stand firm with the unanimous findings of countless mathematical and practical analyses which show superposition of and no interaction between waves or fields in a linear medium.

(*) By "interaction" I mean that one beam or wave has an effect on the other, altering it in some way -- for example, causing it to change amplitude, phase, orientation, or direction. I'm not including superposition, that is the fact that the net field of the two waves is the sum of the two, in the meaning of "interaction".

As far as I know, nobody has been able to do this. But I see that hasn't done anything to dampen Cecil's claims. Apparently having waves be able to detect other waves and bounce off of them when need be is necessary in order to get some other creative theories to work out. So I can understand why it's hard to let go of such a compelling idea.

Roy Lewallen wrote:
> As far as I know, nobody has been able to do this.

Good grief - the *interaction* between two waves that causes
wave cancellation is what makes non-reflective glass work
and has been described tens of times on this newsgroup. Here
it is again:

www.mellesgriot.com/products/optics/oc_2_1.htm

"Clearly, if the wavelength of the incident light and the thickness of
the film are such that a phase difference exists between reflections of
p, then reflected wavefronts interfere destructively, and overall
reflected intensity is a minimum. If the two reflections are of equal
amplitude, then this amplitude (and hence intensity) minimum will be
zero." (Referring to 1/4 wavelength thin films.)

"In the absence of absorption or scatter, the principle of conservation
of energy indicates all 'lost' reflected intensity will appear as
enhanced intensity in the transmitted beam. The sum of the reflected and
transmitted beam intensities is always equal to the incident intensity.
This important fact has been confirmed experimentally."

micro.magnet.fsu.edu/primer/java/scienceopticsu/interference/waveinteractions/index.html

"... when two waves of equal amplitude and wavelength that are
180-degrees ... out of phase with each other meet, they are not actually
annihilated, ... All of the photon energy present in these waves must
somehow be recovered or redistributed in a new direction, according to
the law of energy conservation ... Instead, upon meeting, the photons
are redistributed to regions that permit constructive interference, so
the effect should be considered as a redistribution of light waves and
photon energy rather than the spontaneous construction or destruction of
light."

Two waves interact and their combined energy is redistributed in a
new direction. In a transmission line, the two waves of equal amplitude
and opposite phase cease to exist in one direction. Their energy is
redistributed in the only other direction possible, i.e. the opposite
direction. The conservation of energy principle will allow nothing else.
If reflected energy stops flowing in one direction at a Z0-match in a
transmission line, it must flow in the only other direction possible.

Superposition does not always result in interference but sometimes
it does. Interference does not always result in wave cancellation
but sometimes it does. Wave cancellation is a subset of interference.
One wave cannot be canceled. It takes the interaction of two waves

in order to cancel both and the energy has to go somewhere.

Ditto.

I worked Navy EMI for many years. The US Navy uses a variety of antennas
for HF transmissions on its ships. The hull of the ship and everything in
it conduct the HF, no matter what the antenna. Everything on a ship is
conducting HF at such levels that they're often high enough to interfere
with other equipment.

If Paul Harvey were here, he'd say, " ... and now you know the rest of the
antenna."

That's a tall order. What characteristics of the antennas are meaningful to you? Gain in some particular direction and elevation angle, minimum gain at any azimuth at some elevation angle, pattern circularity, mechanical ruggedness, corrosion resistance, portability, size, weight, SWR at some specific frequency or over some particular band, efficiency? Does it have to have some characteristic(s) when mounted on some particular vehicle? Some point on some vehicle? Some class of vehicles?

What sort of accuracy would make the results meaningful?

Thanks to all that replied. What I am wanting to build is an antenna that will replace the "rubber duckie" one that came with the radio. It is a 2m/70 cm hand held and I found when I replaced the original antenna with a telescoping one on 2m my transmitting distance on 2m improved dramatically. So I am trying to do the same thing on 70cm. I would like to make an antenna that will connect directly to the BNC socket on the radio. Not one that is connected to coax and the antenna erected higher or whatever. I will probably just try a 1/4 wave length connected to the centre of a BNC plug and see how it goes.
Cheers

Correct. On 2M it draws about 8 Amps on Transmit...less on 70cm. HF
and 6M will draw 20 Amps or so. One thing you can do...power it from a
car battery in the ham shack. Take the battery out to the garage and
charge it every couple days (depending on how much you use the radio for
TX)...that would get you by until you upgrade to a bigger power supply.
Or...go into the setup menu and set the RF Power adjustment to
something like 50 (about half power) when you're on HF or 6M.

Further, since Tom said his "B" vehicle in the test is a Saturn, I would not even go so far as to claim that the vehicle is a conductor. The side panels are plastic, though the frame on which they are mounted is metal. Check with a magnet before you drill a hole to mount the base of the antenna!!

Ah, very interesting. So you're saying that the "non-reflective
glass" is a non-linear medium, then. I'm very happy to have learned
that little tidbit. Thank you.

Cheers,
Tom

That is the crux of the issue. The problem as I see it Roy, is that a very well respected (and deservedly so) member of the group has written an otherwise excellent book in which it is proposed that reflectivity is dependent to an extraordinarily large extent upon the way reflective surfaces are irradiated. And further, that these surfaces can change from being partially reflective in both directions to being 100% reflective in one direction and totally non-reflective in the other dependent upon the relative phase of waves impinging upon the surface. I believe that, to a large extent, it is from this idea that the whimsical explanations may have derived.

I am saying no such thing!

If there were anything non-linear about wave cancellation
the result would be harmonic generation but we know that
no harmonics are generated by the *linear* phasor addition
of two coherent sine waves of equal amplitude and opposite
phase collinear in the same direction. In a transmission line,
the energy involved in wave cancellation of two coherent waves
is "redistributed to regions that permit constructive
interference" (per the FSU web page). In a transmission
line, only one other direction is available for the
"redistribution of energy", i.e. the direction opposite from
the direction of the canceled waves, and the resultant
redistributed energy wave continues to be coherent with the
original two canceled waves. There is no non-linearity!

If two waves traveling in one direction in a transmission
line are canceled, their energy cannot continue in the
same direction and that energy cannot be destroyed. Since
there are only two directions available in a transmission
line, it is a no-brainer to figure out which direction the
energy goes.

I agree 100% with the above. Given the surfaces, they
cannot change from being partially reflective. Reflections
from those surfaces are fixed by the *physical* mediums
chosen which result in a fixed *physical* reflection
coefficient. Any reflection coefficient that deviates
from the *physical* reflection coefficient is a
virtual result and is not needed. The virtual reflection
coefficient looking forward into a Z0-match is 0.0.
The virtual reflection coefficient looking backward
into a Z0-match is 1.0. That is the crux of the
problem. Neither one of those virtual reflection
coefficients bare any relationship to *physical*
reality. They are the resulting artifacts of the model
being used and not causes of anything. Virtual reflection
coefficients cannot cause anything. Virtual impedances
cannot cause anything.

I am preparing a picture that hopefully will be worth
a thousands words. I'll try to have it posted to my
web page by tomorrow.

Cecil wrote:
"it`s simply another example of the conservation of energy principle in action."

Yes. When a radio wave encounters a short-circuit, a reflection takes place with reversal in phase of the voltage but with no change in phase of the current. Voltage cancels and current doubles at the short-circuit. Reflection reverses the wave`s direction of travel because only one of the wave`s components has had a phase reversal but not both. Sinultaneously reversing the phase of both wave components has no effect on the direction of wave travel.

Best regards, Richard Harrison, KB5WZI

Source record: 34713

I am very very proud that I hung a 80-Meter dipole about 100 feet above my QTH last week.

But I also had a hankering to cover 40 Meters with it too (although I already had a 40 Meter dipole). So the section in the antenna book about fan dipoles came to mind.

I looked in the ARRL antenna book, it told me that the seperation of wires was not all that important. So I sort-of duplicated one of the sketches in the book, and hung the 40 meter wire from an tiny little egg insulator on the 80 meter wire.

Result: DID NOT WORK AT ALL. No indication of any kind of antenna resonance anywere from 5 to 9 MHz. Sky-high SWR over the whole range. It didn't mess up 80-meter operation, though.

Looked at W4RNL's "My Top 5 Backyard Multi-Band Antennas". The fan dipole is in there, but not in the way it looked in the ARRL book. He says you need a big spacer at the end of the line, like 10 feet, to get consistent results. He has some other notes about modeling Fan dipoles at http://www.antennex.com/w4rnl/col0507/amod111.html I give it a shot, and holy moly, it looks like this should work. Maybe some bigger spacing would result in a bit more bandwidth but I'm mostly working at the bottom of the CW band.

So I'm going to find some skinny 10-foot fiberglass poles and try re-rigging this weekend.

That just proves that you do not understand it
(and never have).

It is the many reflections from the *physical*
impedance discontinuity with its physical-based
reflection coefficient during the transient state
that add up to the final steady-state result. No
reflection coefficients are required besides the
original single fixed physical reflection coefficient.

The first transient internal reflection reduces the
magnitude of the external reflection an amount predicted
by the irradiance/interference equation. The same thing
happens for subsequent transient internal reflections.

Feed it with 450 ohm ladder-line and you can cover 40m
simply by changing the length of the ladder-line with
no tuner required. Please reference:

I am trying to measure the width of an S band pulse. The circirt consist of a transmitter wave guide and the dummy load with two identical directional couplers mounted abot 4 ft apart. The pulse width measured at the DC closest to the transmitter is measured at 1.05uS Measure ment is made through the 20 db port on the coupler a 20 db pad, doide detector good from .1MHz to 12Ghz. 100Mhz scope calibrated in the last week.. Same results with another scope.

the other point of measurement uses the same type DC, connection to the 20db port then a 3db splitter then 20 db pad then the detector and pulsewidth measure .96uS. VSWR is 1.17
Other port on the 3db splitter has a 30 db pad

What could account for the difference in pulsewidths at the two ports.

Jimmie

so on the 2nd port there is an extra 3db splitter. have you tried it
without the splitter so the same load is on both ports? Do the pulses both
look the same shape? more rolloff on the one on the second port maybe?
perhaps a lower sample power is changing the diode response, that is the
detector may not be completely linear. when you measure the 2nd one do you
remove the detector from the first port and move it? or do you have a 2nd
detector that is always hooked up on the 2nd port? If you move the detector
maybe it changes the load at that point enough to affect the pulse shape at
the 2nd port?

I found that if you spread the wires apart 12 inches, as close to the feed point as possible and keep them apart 12 inches (there will be some saging between spreaders, I use 1/2 inch pvc) I have no problems with a 3 wire fan. One note: I do not run A true fan, my wires are hung under each other with the longest, roughly a 66 footer, each side from the feed point. I hung my next longest wire under that one and so on.
I also use an airwound choke at the feed point.

I've been running those for years. Placing the wires closely together
is a problem as far as coupling, and it almost always effects the
higher of the used bands.
The best way to orient is at right angles, if looking from overhead.
At right angles, there is basically no interaction at all, and the
dipoles act pretty much the same as if separate.
In fact, I've had legs fall down and have no effect on the other
bands. The closer the wires, the more coupling, and the more
tweaking you will have to do to get the higher band tuned.
I've even seen cases where the higher band would tune
a higher frequency by adding more wire. Exactly the opposite
from normal. I don't really like having the wires in the same plane
at all, but if no choice, I would use as large a spreader as possible.
I often have multiple bands.. Here at the house, I presently have
an 80m turnstile, and a 40 dipole on the same feedline.
At my place in OK, I have 160,80,40 and 20m on the same coax
feed. All wires spread as far apart as possible. Looks like a big
spider from overhead.

Hello Group,
I am currently restoring a Hygain 18AVt vertical antenna for our local AR club.

I have dis-assembled the bracket on which the feedpoint is mounted. I have discovered that the centre conductor of the SO239 to the first vertical member is fed with a short length of braided copper.

My question is, should I use a piece of braid or stranded copper wire, or a piece of solid copper wire in a 1/2 turn coil to minimise any strain on the joints?

I was led to believe that braid isn't a good earthing medium and wonder if the same applies for feeding RF.

The maximum transmitting power won't be over 200 watts.

I would appreciate some input here.

If you want to argue technical points, please stop
the obvious mind fornicating techniques. There is
actual interaction, i.e. permanent wave cancellation.
Do you know of any way to achieve permanent wave
cancellation without any interaction between the
waves?

Just falls out of the fact that while there's no voltage (the perfect
conductor enforcing a constraint of E=0) there can be current flowing,
so there can be a net magnetic field.

of such cool stuff are things like the reversal of CP sense made.

Here's the deal. If you put the wires close together you get a lot of interaction. The manifestation of the interaction is that the higher-frequency dipoles end up considerably shorter than normal, and they'll have a narrower bandwidth than an isolated dipole. The longest one will also be affected by the others, but not nearly so much. You'll also find that small differences in spacing can have quite an effect on the dipole resonant frequencies, which is why a cookbook approach usually doesn't work unless the writer is very careful to document the antenna accurately and you're extremely careful to exactly duplicate it. But you just about always end up having to tune it.

Tuning a close-spaced multiple dipole like this is time consuming. You begin by adjusting the length of the longest one to resonance. Then you adjust the next shorter one, and so forth. It might be necessary to repeat the process after the first time through. And, as I mentioned, you'll end up with some pretty narrowbanded antennas, and the lengths won't be what common formulas predict.

The interaction decreases rapidly as you spread the dipoles apart. If you can get them around 30 degrees apart, the interaction is minimal and you can just about treat them like separate dipoles. A lot of installations fall between these extremes, so the dipoles have some interaction but it's not as severe as it is when they're very closely spaced.

Roy,

My experience confirms what you report except for the bandwidth but
I did use a balun. My elements are spaced about 7 inches apart and
run parallel to each other. The elements are for 10, 15, 17, 20 & 40
metres with pretty effective operation on 6 and 12.

You can see the figures for the elements here:

> the same spot?

You betcha...

In fact, move that antenna around on the SAME vehicle and you'll get
huge differences in field strength in any particular direction.

The vehicle is more than half the antenna. Not only does it sort of
form the "other half" of the dipole, it's also a big capacitor coupling
to the earth underneath.

Figure a car is about 3 meters long and 2 meters wide (6 square meters)
and it sits about 15 cm off the ground.

C = epsilon * A /d
We can use the permittivity for free space, 8.8 pF/m
C = 8.8 * 6/.15 = 350 pF (approx)

On 40m, that's an impedance of about 11 ohms, which is fairly small,
when you think about it.

On 10m, the impedance to the ground is even lower (3-4 ohms), so it
starts to look like a vertical over a ground plane.

From an electrical standpoint, any of those are equally good, with the possible exception of the half turn option. Braid has more RF resistance than an equivalent flat or round conductor, but it'll be negligible in this application. Putting a half turn in the wire will add some reactance, which might possibly be noticeable on 10 meters depending on the wire length and size of the half turn. If it is, it'll affect resonance but won't have an appreciable effect on efficiency.

And I understand that EZNEC will run under some versions of the Wine
emulator.

It's refreshing to see a Linux user who realistically understands the
price of using a non-mainstream operating system, rather than expecting
software developers to spend the time and resources to develop products
for a very small market.

Proceed, certainly. But know that while the ever-present rubber duckie is a serious compromise at 2m, it is more nearly appropriate for 70 cm. Thus, improvement over the rubber duck is more likely to be seen at 2m than at 70cm.

You might try using a small capacity hat -- at the risk of poking yourself with it, so be careful, there.

>
> - Show quoted text -

I thought about that thw extra 3db may make some difference but I cant
take it off without taking the equipment down. I have a variable 100db
attenuator and I think I may do some experiments this weekend and see
what kind of effect changes in power level will have on the measured
pulse width.

OK, the graphic is at http://www.w5dxp.com/thinfilm.gif
It is the beginning of the transient state. The drawing
is offset for illustration purposes but assume the laser
beam and all the reflections are collinear.

There are times associated with events:
t0 is when the laser is turned on
t1 is when the laser beam first reaches the thinfilm
and the external reflection takes place
t3 is when the first internal reflection reaches the
thinfilm

Questions: What is the power reflected toward the source
between t3 and t5? What happened to the 0.01 watt of
external reflection? How did the reflected power decrease
unless there was partial wave cancellation? What is the
steady-state reflected power toward the source?

Actually braid has muxh less 'resistance' than a flat or round conducor at
RF due to greatly increased surface area and skin effect.

With just a few easy modifications you could change your 80 meter dipole
into a G5RV and cover nearly the whole ham band including 40m. Despite what
you may hear from some disparagers, G5RV is actually an excellent antenna.

Sorry, that's simply not true, except at lower frequencies where the skin depth is comparable to the wire diameter. It's at those frequencies that Litz wire can provide some advantage. But it's made of separately insulated strands. Because of skin effect, the current at HF (or wherever the wire diameter is at least several skin depths) is only on the outside surface of the braid, not the outside surfaces of all the wires. The extra loss comes from the necessity of the current moving from one set of wires to another as the original set goes under an adjacent group. Surface roughness in itself can significantly increase RF resistance (cf. Johnson and Graham, _Signal Propagation - Advanced Black Magic_, Sec. 2.11), but the braid structure increases the resistance more yet.

I know Tom, W8JI, has measured the impedance of solid strap and compared it to braided shield, and confirmed that the shield has substantially higher RF resistance. I don't see measurement results on his web site, but he briefly discusses the phenomenon at http://www.w8ji.com/skindepth.htm.

One other note - for the same surface area, a round conductor has the least RF resistance of any conductor shape. The reason is that the current is evenly distributed on the surface. On other shapes it's not, resulting in higher resistance per unit length.

Roy
I apologize for being so cryptic. I'm interested in determining the efficiency of the antenna in projecting the available power out to local horizon in all directions. I'd rather not have to aim the vehicle in order to raise a distant station or repeater. I bought the highest gain vertical I could afford which is a Comet SBB-7. It is supposed to have a gain of 4.5 dbi. It is mounted on a lip mount on the back left door of the Chevy Express 1500 that I use for bread work and radio public service work. I'd like to know whether it is worth deploying a collinear J-pole on the roof of the van when I'm stationary. Is the mobile antenna doing it's job well enough that there is not enough to be gained? The things I'd like to be able to test are is the power actually getting to the antenna, which antenna puts out the strongest horizontal, or nearly so, circle and so forth.

If individual photons interefere with one another, why is the antenna pattern independent of power?
More specifically, one gets the same pattern if photons are emitted one at a time.

In fact, when photons are coherent (MASER, LASER), the appropriate term is hologram.

I would love to have coherent photons at HF.
Infinite F/B and a beamwidth of zero.

The higher RF resistance of braid is very noticeable in tube power amplifiers at HF, where the circulating currents are magnified by the Q of the tank circuit. If the connections between the coil taps and the bandswitch contacts are made from braid, they can run very hot, while thin strips of solid copper give no problems at all.

For antennas, the main concern about using braid is corrosion, which will insulate the strands from one another and greatly increase the RF resistance. This is why the loss of normal braid-covered coax increases dramatically if water gets under the jacket.

However, the original question was about a very short braid connection in a non-critical application. There must be hundreds of 18AVTs out there, all with corroded braid. Nobody notices the difference, so that proves it's non-critical, right? :-)

The purpose of this braid is to prevent failures of the solder joint to the SO-239 after a few months/years of flexing in the wind. John's original suggestion of a small loop of insulated stranded wire would do equally well - one turn around a pencil, say. Sealing the two solder joints with hot-melt glue will finish the job nicely.

The tiny additional series inductance will not be significant at HF.
When the elements are adjusted to length, it will vanish completely.

Pretty good on 80m, 40m, 20m, and 12m. Not very good
on 30m, 17m, 15m, and 10m.

http://www.cebik.com/wire/g5rv.html
http://www.vk1od.net/G5RV/
http://www.w8ji.com/g5rv_facts.htm

On 75m, putting a 1200 pF shunt cap across the 300 ohm
feedline at the balanced to unbalanced junction will put
the resonant point in the phone band and result in very
close to an SWR of 1:1 on the coax. The cap needs to
be removed for 40m operation.

<snip>
==========
It all depends what feeder you use.
When using twin feeder and a matching unit to suit both such a feeder
and the traditional asymmetric 50 Ohms output of any
transmitter/receiver , an 80m dipole,or a dipole of any length for that
matter, can be readily used on 160 m provided that half the dipole + the
length of the feeder is roughly an odd number of quarter wavelengths at
the operating frequency (assuming the velocity factor of the feeder is 1)
In this situation the current in the twin feeder at the matching unit is
relatively high ,hence the impedance is low ,because the voltage is
relatively low (hence no crackling/corona problems.

Cecil Moore's web site shows how he adds lengths of twin feeder to suit
the different bands.

Vector (phasor) addition is necessary but *not sufficient*
for wave cancellation to occur. For wave cancellation to
occur, the two waves must be coherent, equal in magnitude,
opposite in phase, and *collinear* in the same direction.
Vector (or phasor) addition can occur with or without
"interaction". Wave cancellation cannot occur without
"interaction" between the two waves.

If the two interfering coherent waves survive the interference,
they did not "interact" probably because they were not collinear.
If the two interfering waves do not survive the interference,
they interacted, were canceled, and their energy was "redistributed
to regions that permit constructive interference" as described on
the FSU web page.

H. Adam Stevens wrote:
> I would love to have coherent photons at HF.

The feedpoint impedance of a standing-wave antenna (like a dipole) is (Vfor+Vref)/(Ifor+Iref). Since the Z0 of a dipole wire is in the ballpark of 600 ohms, the interference that results in a feedpoint impedance of 72 ohms proves the photons are coherent.

If the SWR on 450 ohm ladder-line is between 4.5:1 and
18:1, the impedance at a current maximum point will be
resistive between 25 ohms and 100 ohms for an SWR on
50 ohm coax of 2:1 or less with no tuner. See the Smith
Chart at: http://www.w5dxp.com/smith.htm

I have had the same experience.

It turns out that more spacing is better and cut & try is better than
thinking too much about what you have. Consider extending the shorter
elements with nylon line to the end supports rather than hanging them
on separators. Fans work well as verticals too!

If you drop the end support it will tangle faster than a closet full
of coat hangers...

Ian
Reading the two analysis on braid and RF. It seams to be missinbg
something
or I have things totaly wrong about this. With multiple wires with DC
the
resistance will go down but with RF you have competing SLOW WAVE
phenomina,
bevause each wire is now insulated from each other which prevents wire

hopping.
In other words the corrossion or insulation would DECREASE resistance
would it not? If it is used as a dipole I can see the IMPEDANCE going
up since
the radiator lengths has DOUBLED!
As far as skin depth is concerned I would imagine/think the skin depth
is some what altered
because of the compensating increase in area exposed to RF despite the
fact that
braid presented only half of its useful area!
Could you please point out the errors in my logic?
Regards
Art

Ian, to put things more clearly the model I was analysing
was for the frequency rate of 1 Mhz where the analagy was
the use of Litz wire where slow wave contra helices were introduced
and where radiation only oceres in places where the wire is
exposed to the air.

Gentlemen
You guys are really screwed up with respect to radiation
A radiator has three components, capacitance, inductance and
resistance
where Maxwell states thatthe RC ratio is a constant for the material
and frequency.
All of these three components store energy in diffent forms. Now the
capacitor
stores static energy via static electrons and there is no getting away
from that.
Maxwells laws state that the LC ratio must be kept for the model used
and we
know that the expellation of energy with velocity is only by the
capacitor
and the inductance acting asd a tank circuit. We also know that a
diagmagnet
material is a radiator that has bound electrons in orbit around the
atom but it is also
one of the few materials that allow free static electons to rest upon
its surface.
Now you take it from there. A wavelength radiator with free electons
resting on its surface
and subject to two high velocity energy release explosions per one
cycle.
Now where in the heck do "protons"come into play when we are forcing
static
electrons off of the surface of a radiator by overcoming its inertia?

Another point Using Gauss's law of statics we use only static
particles in a field.
There is no reason why we cannot add to the field a resonant length of
a radiator
as long as it doesn't upset the equilibrium inside the field.

(This arbitary border system is used widely in many areas of
matematics)
You can then add to the model a time varying factor which duplicates
Maxwell's equations and solve by a Maxwell derived computor program
which
allows one to deduce that a radiator can be any shape or size or
configuration
as long as it is in equilibrium inside
the Gaussian field.
Again we see a instance of radiation where the static particle or
electron
is the main subject of radiation. Again no reference to protons!
Look up google regarding atomic explosions where it is stated that
electrons
impinged on the Hawii electrical system and crashed it. Electrons
were
ejected thru the atmosphere, again with no mention of protons.
Why O why do hams try to make things difficult? I defy anybody
to finding things to the contrary with respect to mathematics
other than just hand waving so what is ham radios problem?

Yes you can if you are looking at magnetic fields which is a measure
of reactance.
But the phenomina that produces the magnetic field is still there and
must be
accounted for and that is the slow wave phenomina

A bit more on the lack of "interaction" between two waves...

Consider two electromagnetic (EM) waves, originating from two distinct sources, that share some common volume of space*. If you wish, consider only a very narrow portion of each wave, so they might be called "beams" much as you'd get from a laser pointer. Consider where these beams cross each other at right angles. There is no "interaction." The beams do not bump into each other and scatter off in different directions as billiard balls or as streams of water would do. The net instantaneous field strength at each point in space, for both the electric and the magnetic field, is simply the sum of the components from each wave. It's a vector sum, because each component has a magnitude and a direction in space. Beyond the point of crossing, each beam is present exactly as it would be had the other beam not been there. At least, that is what I observe; perhaps I'm not observing closely enough. Perhaps there is some interaction that affects the beams in a way that I could measure if only I were measuring with enough resolution; but sensibly there is no effect on one beam from the presence of the other. The beams may be identically the same frequency in any relative phase, or may be different frequencies, or may be a complex assortment of frequencies. One could be visible light and the other a 20kHz radio wave. It wouldn't matter; there is still no observable effect on one beam from the presence or absence of the other.

If I then consider beams which cross at other angles, I observe the same (lack of) effect, one on the other. My representation of the net field as a simple vector sum of the instantaneous fields from each beam, for each point over all space, for each instant in time, still accurately describes the situation.

In fact, if the beams are identical frequencies and exactly aligned in the direction of propagation, what I observe still conforms exactly to the description where the beams crossed; the net field at every point in space for every instant in time is the vector sum of the fields of

the component waves. I didn't have to invent any new math to describe the situation. To the extent that there was no interaction in the first case considered, with crossing beams, there is also no interaction in the case of beams exactly aligned. Nothing magical happens, and no new concept needs to be introduced for this case.

We may indeed need to introduce new concepts if we discover that, at high enough amplitudes or with careful enough observation, there really is an interaction and our model of simply adding vector fields is not sufficient. But I fail to see the need to do that in the situation described here.

It is no "mind game"--it is an IMPORTANT concept that the fields do not "interact;" they simply sum. There is NOTHING NEW required to consider the case where the beams HAPPEN TO BE identical amplitudes and exactly out of phase at every point in time and space in some particular region.

*In all of the above, I have considered that the waves are travelling through space containing nothing but electromagnetic waves; there are no free electrons or ionizable molecules in this region. My observations lead me to believe that such space is a linear medium.

How do YOU make it flow vertically along the sides of the car and not
distributed along the whole conductive surface of the car's body? How do you
make the current flowing, say, towards the front of the car (or one side)
not to (partially) cancel by current flowing in opposite deirection, towards
the back (or other side)?
The currents flow from the feed point, base of the vertical in all
directions where supported by conductive sheet metal, or wire or radial.
They might not be exactly symmetrical, but they have opposite direction
portion of the current and corresponding cancellation.

How simple! :-)
Please model vertical resonant dipole, then monopole with one radial, then
with two radials, then with 8 radials, then with 64, then with solid sheet,
then with car body. Then move the antenna around, away from the center and
see what happens to the pattern. See how this "conductor" is "another".

Then the case of say 2m quarter wave vertical mounted in the middle of the roof, sure doesn't look like car is the other wire.

That is true, but portions of the current flowing in different directions from the feedpoint are in opposite direction and based on their magnitude partially cancel. The result is the interaction with monopole, radiator and forming the radiation pattern, which in practical HF mobile installation is distorted, lopsided. If it was the"other wire" then it would be symmetrical like in true vertical symmetrical di-pole.

I am not suiting myself but describing difference between vertical monopole working against conductive surface (sheet, car body, radials) with corresponding current flow and dipole, di-pole that customarily refers to symmetrical antenna with two (similar) legs.

Sounds more like "Roy special" - everything is assymetrical or symmetrical dipole. How "dipoly" is the 2 m whip in the middle of the car roof? How can

you tune to resonance 80 m car whip by adjusting the "other wire" - car body? Implying the other half of "Roy dipole" is a "wire"?

This thread has taken on a life of its own since I posted my first
question. I really don't understand any of this. I thought that I wanted
an antenna with zero reflected energy or as close to that as possible.
Now it sounds like that is not always the case. I need to learn all
about SWR and impedance in regards to Antennas, from start to finish. Is
there an easy-to-read tutorial out there for a beginner like me? Maybe
Ham Radio for Dummies has something about SWR and antennas?

I don't make it flow anywhere. The field from the current flowing toward the front, along the roof, cancels the field from the current flowing toward the rear along the roof. Once the current reaches the edge of the roof, all components flow vertically. If the car is symmetrical and the antenna mounted in the center, all components are in phase. There is no field or potential gradient to induce current flow horizontally along the sides, front, and back of the car.

> The currents flow from the feed point, base of the vertical in all

Along the roof, yes, as I explained in my original posting. But they don't flow in opposite directions along the sides, front, and back of the car.

If you're saying that a car doesn't look like a 19 inch wire, you're
right. It doesn't look like the Earth, either.

Sigh. You're right, it's not like a symmetrical dipole. It's like a Yuri
Special asymmetrical dipole.

My comments were made when envisioning an HF antenna. I believe that if
you move the same HF antenna from one car to another, or change the
mounting position, the resonance will change. Haven't you found this to
be true? At VHF the asymmetry is of course much greater, and the short,
thin part (the whip) of a structure like the VHF whip-car combination
has much more effect on the impedance than the long, fat part (the car).

You're not alone. SWR and transmission lines are widely misunderstood, even, I'm sad to say, among many engineers working with RF. Because of the widely held misconceptions about these topics, writers of some of the tutorials and discussions which have made it to print have also fallen victim to mistaken concepts. I'd be especially leery of explanations found on the web. While surely there are some which are entirely correct and very well done, I'm certain there are many others which aren't.

I recommend the _ARRL Antenna Book_ as a good place to start.

Hi James,

Little wonder.

You asked a few questions:

1. Hi, I am learning about antennas, and and wondering about how antenna
tuners work. I've read you can use anything as an antenna as long as you
have a tuner.

2. Well, If I put up a wire dipole, and then use a tuner, what is the
best length of wire to use?

3. If I use an 80 meter dipole with a tuner, is that better than using a
10 meter dipole with a tuner?

My offering is:

1. That is a very simple statement, and for instance does not address
efficiency or a host of other issues (eg EMR safety). It is a restatement
of the popular ham maxim that "anything works" or the "any antenna is
better than no antenna".

2. The elements of an antenna system have a complex interaction, and
system performance can only be understood when the entire system is
analysed as a system. That means you have to start at the element level
and gain an understanding of those and then how they interact in a
system. Another popular ham maxim is "bigger is always better", it is
easy to say, but is doesn't apply in practice and is usually stated to
mask a lack of fundamental understanding.

3. You are a bit more specific, but not specific enough to answer
definitively. A half wave dipole fed with a balun and a reasonable length
of appropriate coax is an antenna system that takes only moderate
knowledge to design, fabricate, install and set to work with a high level

of confidence that it is working reasonably efficiently. You may even wish to use an ATU (which is essentially an impedance transforming network) for small optimisation of the load impedance seen by the transmitter.

Whilst the temptation to use the antenna system described at 3 on multiple bands may be great, and it is done, the outcome is often very poor. For example, such an antenna designed for 80m (system efficiency should be greater than 80%) is likely to be well less than 10% efficient on 40m.

Be ware of simple Rules Of Thumb, there are often a plethora of unstated assumptions, which when considered make them ROT.

Owen

If you can't contribute anything positive to this question, then stay out of it, with your trash!

I have a 10m base loaded mag mount antenna, that I had to put a piece of felt over the magnet as not to scratch a new vehicle.

When I did this I apparently changed the capacitance between the mag mount and the roof of the vehicle. Someone suggested that I might want to replace the felt with either a large balloon or a large prophylactic as it is thinner and the capacitance would then return to almost where it should be.

Positive comments only!

How do you define excellent? Why would one need to change the length
of
the element, just to feed it on all bands using a tuner?
Of course, there are quite a few variations of the G5RV, but I've
never seen
on that I thought was excellent. The ones I used at field day two
years in a
row were totally pathetic. But of course, they used all the usual
garbage
between the rig and the antenna as they are usually sold.
Rig to tuner to coax to choke to twin lead to element.. What a
mess... :(
Too much loss with all that junk.
He would likely be better off keeping the same element length, and
feeding with nothing but twin lead from a tuner if one wanted to use
it on all bands.
But his current plan of separate dipoles feeding with coax is better
than either one as far as efficiency. He will also have pretty much
a dipole pattern for each band also. This is usually better when used
for lower band NVIS type paths, vs longer wires that have more gain
in
certain directions. If you have gain in certain directions, you will
lose
some in other directions. This is ok in some cases, but not so great
in
others. I'd rather have the broader pattern on the low bands for NVIS
use.
If I was Tim, I'd stick with what he has, and just get it tuned. Once
he does, he won't have to mess with it anymore, and it will outplay
most other types of multi-band setups. No tuner fiddling changing
bands either.
It will smoke the usual garden variety G5RV kits that are sold.
My experiences using the G5RV were so poor, I refuse to ever
use one again. I'll go back home and watch TV before I'd ever get
stuck on one of those again for 80/40m field day use.
It was horrible.. I felt like I was using a dummy load for an antenna.
No joke.. But like I say, these were the basic store bought G5RV's
including all the lossy junk. It's possible to dump most of that

junk and have a decent antenna, but I would still prefer the parallel coax fed dipoles. For multi band use, I don't think they can be beat for overall efficiency. I use nothing else here, and have been going that route for years. But I am kind of anal about unnecessary system losses.
MK

John

I would have thought that the felt would make the mag mount more likely to slip against the roof. You might not get any scratches, but you probably would be minus one antenna at the end of a fast drive.

I have had good results using strips of insulating tape or adhesive backed plastic type materials, similar to the stuff they print stickers on covering the magnet. For best results, you want a soft resiliant type of plastic, something that wont slip against the roof metal. Or have a look for some of that plastic sheet that sticks to glass and smooth surfaces and is used to secure licence or insurance details to car windscreens. That should protect your paintwork and be removable at a moments notice. A favourite trick for mincab or unlicensed cab drivers is to cover the antenna base with a stout sandwich bag and secure it in place with a plastic tie wrap. Take the antenna off the roof and no traces left behind.

Any of the above methods should work okay and they will all be a lot thinner than a piece of felt.

Mike G0ULI

It is obviously difficult to get two light beams
traveling in a collinear path. That's the reason
you have not observed wave interaction. If it
were possible to get two coherent laser beams
of light traveling in exactly the same path in
the same direction, what would be the result?

Two coherent beams of laser light of equal amplitude
and opposite phase traveling forever in exactly the
same path. What would happen under those ideal
conditions?

Getting waves collinear in a transmission line is
easy.

"The ARRL Antenna Book" is a pretty good start.
Here's a matched antenna system with an SWR of 9:1
on the ladder-line. Understanding this system will
be a step in the right direction.

> be true?

Actually, on mine, I don't see much difference in the resonant point
of the whip from car to car. Just the degrees of loss, depending
on the mount location.
IE: I ran my usual HF antenna on a chevy monte carlo for
quite a while. It was mounted on the trunk, and the car
body forward of the whip was a good bit longer than to the
rear.
I stuck the same antenna on one of my trucks, with the whip
mounted on a piece of angle iron bolted to each side of
the toolbox/bed right behind the back window.
The tuning was basically unchanged.
But the efficiency was poor.. :(
I came to the conclusion there was not enough metal
under the antenna base, so I moved it to the side toolbox
where there is a much wider strip of metal under the
whip vs the narrow angle iron.
That pretty much cured the problem, but didn't effect
tuning much at all
Then I mounted it on another truck, but this time on a
ball mount bolted to the side of the cab.
Again, the tuning changed little. The antenna worked
great, and that truck has the highest mount, and
good metal at the base of the whip. I consider it the
best of my vehicles for mounting an HF antenna.
But then I later tried mounting it on the trunk of my
honda accord. Again, little change in tuning.
It worked fairly well. About like the monte carlo,
except maybe a tad less efficient being the car
is smaller. On those 4 vehicles, I never had to do
any drastic changes as far as tuning the whip with
the number of coil turns used.
One thing that bothers me about the mobile antenna
= a perverted dipole theory..
You would think that the amount of metal under the
whip would not matter too much in that case as long
as the connections are real good.
But.. This was not the case. The amount of metal

under the whip seems to be quite critical.
So... This makes me believe the antenna acted more
like a typical short vertical, than a offset dipole
even if trunk mounted.
As with a typical ground mount vertical, the amount
of metal under the whip seemed to be critical.
IE: most suggest more short radials, vs long ones,
as it gives more metal under the whip.
The typical HF mobile seems to act about the same
way.
I don't doubt that the pattern with a rear mount is
a good bit different than a roof center mount though
due to the "dipole" effects of the offset mount.
But I've never seen the tuning of the whip change
much between those four vehicles I mentioned..
I use the same "fixed" coil taps on all of them.
I still haven't tried mounting it on my newest car
"toyota corolla", as I'm still chicken to bugger it up
and drill holes in the car. :/

As part of the amateur license exams you will run into complex impedances
and perhaps even a few questions about what a smith chart is. My advice is,
once you learn how to graph complex impedances on a simply x-y plot, all
you need to realize is that a smith chart is a graph just like this except
but x AND Y DIMENSIONS ARE TURNED INTO THEMSELVES AS CIRCLEs OF FINITE
RADIUS rather than as circles of iinfinite radius. That circular graph lets
you perform all sorts of tricks such as plotting for SWR or plotting for
impedances that result in a certain SWR. It shops you how/where a
transmission line changes its inductive/capacitive impedance along its
length expressed in fractions of wavelength, making it easy to calculate
transmission line lengths to match certain antennas at desired frequencies.
You can go http://sss-mag.com/pdf/smithchart.pdf to download a good pdf copy
of a smith chart. Just gaze it it for a while and play around with it. You
will see that it is better than a digital computer in many ways for
achieving what otherwise would be complex calculation tasks.

I guess in my case, the G5RV is the best I can do. I live in a restricted PUD but I have a 'relatively' large attic. I could fit a bent 80m dipole up there or a bent G5RV that is just a few feet shorter. But with the G5RV, I do get some good performance on several ham bands and I think it is more efficient than the 80m dipole because the ladder line also functions as part of the antenna (as you know, according to G5RV theory). Including the ladder line gives me 'more' vertical antenna, at least of somewhat predictable radiation characteristics. I have said elsewhere that what I really have up there is a "fractal" G5RV that radiates in segments but that is just a joke of course. My neighbors are completely unaware of my 80/40/20 m antenna in my attic that also works at other frequencies with lower efficiency. I can operate at 80/40/20 at about SWR=3:1 although I use the tuner anyway to prevent my xmitter from folding back due to SWR. I am sure I have no defined lobes but I know from experience that my radiation angle is much less than 90 degress in most cases. But I also must defer to yourself and others because this is a technical group where we get into more than "how stuff works.com"...I participate if I think I can contribute in a certain area. Thanks for your comment.

It's not more efficient, but there are cases where the feed radiation
could help if there is a need for some vertical polarization.
But... thats just another of what I consider a problem.
I don't want any feedline radiation. If I want vertical, I'll
run a vertical.
But I realize you are limited on room, so not a perfect world.. :/
If you are using the usual G5RV setup with the tuner to coax to
choke to twin lead, you would actually be better off running the same
antenna, but using only the tuner to twin lead all the way to the
antenna.
In cases of limited room, I usually prefer "Z" dipoles fed with coax
if for single band use. Here at home, I can't run a full length 160m
dipole on this lot. So I used a "Z" dipole fed in parallel with my
other usual dipoles.
I did tests comparing the Z dipole with loaded dipoles, and the Z
dipole always won. This was even with using heavy fat wire coils,
and optimum coil locations on the elements.
If I used a Z dipole for all band use, I would feed it with ladder
line
the whole way.. Or twin lead.. Twin lead is fairly decent indoors as
it never gets wet.
I have a 40m dipole in my attic for emergency use when it's real
stormy. I feed it with twin lead so I can run 40-10. Being it's half
size on 80m, and fed with a T-net tuner, the efficiency is poor on
80m. Lots of tuner loss..

> But I also must defer to yourself and others
> because this is a technical group where we get into more than "how stuff
> works.com"...I participate if I think I can contribute in a certain area.
> Thanks for your comment.

Ya gotta use what you can fit in.. I have no problems with anyone
using any type of antenna. If it works well enough for you, that's all
that really matters.
I'm just warning of losses you may not notice if you don't have a

coax fed dipole to A/B test them to compare..
BTW, I don't just pick on the G5RV's.. :/ I also am not crazy about
most windoms either if they are fed using the tuner to coax to choke
to wire scenario..
I did a A/B test against one of those one time on 40m.
The windom seemed to be working just great. They could hear
stations, and make contacts, and all was well in the world.
But then I hooked up a coax fed 40m dipole, and used an
antenna switch to be able to quickly A/B.
The coax fed dipole brought "everything" up 2 S units.
Noise floor, signals, the whole ball of wax.
I kid you not. The windom guy almost fell over..
He had no idea he was losing that much.
Some may say, well 2 S units ain't much..
But when you consider that the usual change of
running 100w vs 600w usually amounts to about 2 S units
on most run of the mill S meters, thats quite a
bit of loss.. :(
It was like I was getting the effects of a free 500-600 watt
amp vs the windom..
But to each his own, or to his room.. I'm not trying to
be an antenna snob, I just jibber jabber about them..
MPG will vary..

Actually, a Smith chart is just an overlay on top of a simple polar graph of reflection coefficient. (Mathematically, it's a mapping of impedance values to a reflection coefficient graph.) If you plot the value of a (complex) reflection coefficient on an ordinary polar graph having radius = 1, then place a Smith chart over it, you can read from the Smith chart the impedance that results in that reflection coefficient (normalized to the transmission line Z0). That's why, for example, a constant SWR locus is a circle on a Smith chart - it corresponds to a single magnitude of reflection coefficient.

I second Stefan's comments about the value of a Smith chart. It's an excellent tool for visualization once you learn how to use it. But first you need a basic understanding of transmission line principles.

I have heard this statement before but consider it just gossip
I see no reason for the so called "necessity of current moving
from one set of wires to another as the original set goes
under an adjacent group". Neither have I come across any proof
of such a thing happening. The impedance on the current carrying
wire is certainly less than that encountered by jumping a "gap"
so there is no "necessity" to creat corona of any sort, especially
when the current has to take a 90 degree turn to get the job done.
I could change my mind if actual proof was presented,
that is if any exists; otherwise I just view such statements
as a propagation of falsehoods while mismanaging a response.
A case in point, a silver contact on a relay after spending
some time in a cardboard package requires in excess of 24 volts
to break down the oxide so imagine what it would take to break
the oxide doiwn of copper!

There's no theory I know of which causes a G5RV feedline to radiate more or less than any other dipole. The amount of feedline radiation depends on the amount of common mode current it carries, and its length. The amount of common mode current depends on a number of factors, including how the transmission line is fed, how it's oriented, its length, and the common mode impedance of the antenna. This is discussed in some detail at http://eznec.com/Amateur/Articles/Baluns.pdf.

Increasing the amount of vertical radiation and/or having the feedline radiate doesn't improve the efficiency of an antenna. If you prevent the feedline from radiating, the power it would have radiated ends up being radiated by the antenna instead.

In case you missed it, the 500 KW was in the 1930s. 250 KW of audio was not easy to come by. Last I heard WLW was using a Harris 50 KW digital AM transmitter. See http://download.harris.com/app/public_download.asp?fid=1489 . Digital here means that the AM signal is digitally synthesized at high level. There is no modulator.

134. Power supply question

Newsgroup: rec.radio.amateur.antenna
Date: 2007-11-04 00:52:26 UTC
From: Steve <sdaniel13@speakeasy.net>
Message-ID: <1194137546.533253.101210@v3g2000hsg.googlegroups.com>
Source record: 34687

I pulled an old Astron power supply out of mothballs today. It's a 13.8 volt / 20 amp supply (the RS-20A). I find that there's a noticeable hum when I plug it in, and I also notice that a small output voltage of one volt or so is measureable on it even when it's turned off and unplugged.

What should this tell me about the condition of this supply? As it is I'm nervous about using it.

Thanks,

Steve

I stated it improperly. I agree that total radiation efficieny in all
directions does not increase but I believe efficiency as a vertical radiator
(ie in the horizontal plane) does increase with G5RV at some frequencies due
to the ladder line. See http://www.roadkill.com/~unwin/G5RV.html

If you prevent the
> feedline from radiating, the power it would have radiated ends up being
> radiated by the antenna instead.

Of course, this is correct. However, when you're cramped for space and are
trying to get as much RF as possible in the horizontal plane (rather than
warmimg clouds directly overhead :-)), it is advantageous to intentionally
use the vertical ladder line as a radiator when possible. At least, that is
the theory of one who has always had to use attic antennas. Fortunately I
will retire soon and will be moving to a place where I can put up a 160m
horizontal dipole if I wish.

You are wasting your time trying to protect the paint when using a
magnetic mount. Grit will find its way under your magnet, and within
a year of normal driving, you will have scratched paint. Take a deep
breath, get out the hole saw or metal punch, and punch a hole in your
new car. Your radio will be happier and so will you as the paint
around your antenna will not be subjected to the inevitable damage
caused by magnet mounts. BTW, before anyone says anything about
lowering the value of the vehicle, I've sold and traded-in multiple
vehicles with holes punched in them, and not once has anyone ever said
a word about the holes. When I trade it in, I just put in a rubber
plug and no one notices.

However, if you have committed yourself to using a magnetic mount, I
would suggest using ultra thin vinyl sheeting, this should give you
enough grip to keep it on the vehicle. Nevertheless, anything that
you use is going to require that you retune the antenna, a longer whip
may be also be required because of the decreased capacitance.

Ok, it seems like depends on how much power you are putting into the
detector to start with whether or not another 3db matters.

Nice to know it was set up on the hairy edge like this.

Lose the magmount and drill a hole in your roof. When you sale your
truck put a rbber plug in it made for that pupose. Has 0 effect on
your resale value.

140. Re: Supposed comparison of Mobile HF Antennas in November QST

Exactly!
Vertical mounted on a conductive vehicle body behaves as a vertical monopole - radiator working against the ground plane - car body. It is apparent that the idea that car is the "other half" of "asymmetrical dipole" is misleading and not applicable to the case. Mobile antenna behaves like any other vertical monopole over conductive ground plane, radial field, radials - regardless of their size and definitely not as the other half of "asymmetrical dipole" and practically not affecting tuning, which is the case with any real di-pole.

The thickness of the balloon will result in a much larger capacitance to the
'ground' plane counterpoise so it should be a big improvement over the felt.

This is an old linear supply (I have one too). It could be that due to years of non-use, the electrolyte in the big filter cap dried out. The 120 cycle hum could be the current through the transformer being overloaded by foils that are shorted in the cap. In any case, you said 'mothballs' so it probably wasn't used for a long time so it might be a good idea to replace the filter cap. Buy one of similar C and V rating online or maybe you can even find something similar at radio shack.

I'm afraid you're misinformed. The dielectric constant of PTFE Teflon is 2.1, or just about twice that of air. Quite a few plastics are higher (e.g. Mylar at 3.2 and PVC around 3.5), and many materials, such as those used for capacitors, have dielectric constants that are a lot higher (e.g., barium titanate at 1500 - 2000). Of course, a lot of the latter aren't physically suited for this application. A long time ago, I had trouble with microstrip line dispersion in a high speed delay line compensation network design. So I chose Teflon for the substrate material because of its *low* dielectric constant. The previous design was on an alumina substrate having a dielectric constant of about 10.

The capacitance of two parallel plates is directly proportional to the dielectric constant and the plate surface area, and inversely proportional to the plate spacing. So putting 0.1 inch of Teflon between the plates gives you the same capacitance as putting the plates 0.05 inch apart with air between.

This isn't to say that Teflon might not be a good choice. It's a very low loss material, and chemically very inert. It's soft so won't scratch, but it's slippery which might be a disadvantage. It's also subject to cold flow, but there probably won't be enough pressure for that to be a problem.

I think that when considering plastic and mica type materials for high capacitance values, component engineers do not necessarily look at dielectric constant as the most important property. Mylar, mica and polyethylene are common capacitor materials and have rather low dielctic constants just a little higher than teflon. What makes them most attractive is their ability to be manufactured in very thin sheets (increased C) and their high dielectric strengths (increased V ratings). Teflon is higher cost but is very good for high voltage ratings due to superior dielectric strength.

Aluminum and tantalum oxides tend to have very high dielectric constants due to the capability of these metal oxide molecules to store electrons. What is more desirable however is their property of being very thin. What makes them a problem is their relatively low dielectric strengths thus their low voltage ratings.

Oh, no, you've been reading Art's postings! He uses the term "efficiency" in creative and inscrutable ways.

When used with respect to antennas (and a lot of other things), "efficiency" has a universally understood, precise definition. The efficiency of an antenna is the ratio of the power radiated to the power applied. What you meant was effectiveness, not efficiency. If you do find it necessary to use "efficiency" to mean anything other than what it's universally understood to mean, you'll need to carefully point this out at the time, or people are bound to misinterpret what you've said -- as I did.

So what you're doing is intentionally making or allowing the feedline to radiate in order to get some vertically polarized radiation so you can get more radiation at lower angles from a low antenna. That's a method some of us would avoid, but in circumstances like yours it's very likely one of the best solutions available.

don't mean to go off topic, but I bought a new hyundai in 2000, and it
came from the manufacturer with a hole in the roof! Roof antennas seem
to be popular for cell phones and GSP. It had one of those plastic
plugs, and it looked perfectly normal.

I've been down that road, too. The mag mount is OK for short term use, say
for a day or so but it is not a good idea to leave one on the vehicle for

any length of time. As Dloyd pointed out, grit WILL find a way to get under the mount and it WILL damage the paint. I learned the hard way that moisture will also linger under the mount and the paint will be further damaged. Then, too, is the possibility of the antenna striking branches, door tops and other low-hanging obstacles and when the magnet slides across the roof, guess what? You got it! More damage to the paint.
At VHF/UHF frequencies you will not see enough of a change in the standing wave to be concerned with if you use a buffer between the magnet and the body. It will be miniscule.
Dloyd is correct again when he advises you to do it the right way. Drill a hole. Mount the antenna and have fun.
Oh, as an addendum? I once had a magnetic mount antenna stolen from my car. It was a 2 meter quarter wave whip but that didn't phase the CBer who cut the coax and stole it. And before you jump on me and ask how I know it was a CBer, read on.
I had engraved part of my soc number on the underside of the antenna. I just happened to visit a local CB shop one afternoon and saw my antenna on a shelf and the owner of the shop told me it was for sale for five dollars. Without going into further detail, I arranged for a local detective to visit the shop and buy the antenna, whereupon the owner of the shop was promptly arrested for selling stolen property. The icing on the cake, so to speak, was when the detective discovered that the owner also had several stolen CB radios for sale as well. The CBer who stole the antenna was also caught and charged.

I don't see what the big deal is. I have a mag mount on my car and
haven't noticed any scratches. It doesn't move at all. It is a 2 meter
antenna, and the magnet is very strong. Do other mag mounts typically
have week magnets?

Actually, there are a lot more considerations yet. Some plastics are self-healing, so a momentary arc won't permanently destroy the capacitor. And some have exceptionally low leakage current. Various materials also have widely different temperature coefficients. In general, the very high k (dielectric constant) ceramics have higher temperature coefficients than lower k materials. Some ceramics, like the very high k ceramics used for Z5U and similar capacitors, are also hygroscopic, microphonic, piezoelectric, and their k varies with frequency and voltage. Many capacitors, depending largely on the dielectric, also have nonlinear properties such as "soak" (dielectric absorption) and "hook". Loss, expressed as loss tangent, ESR, or power factor, is also often an important consideration, and it can be very different for different dielectrics. Choosing the right capacitor for a particular job can be pretty demanding. This one, fortunately, is easier than some.

At least one dualband magmount, no longer offered by MFJ, came with an
aluminum foil bottom. I have used several of them and seen no adverse
effect on the paint -- and I whiz along at highway speeds a lot.

> Now it sounds like that is not always the case.

You were mostly right; this is the theoretical ideal, but reality forces compromises on all of us.

To put it simply, yes, you want the most power to "jump off the antenna" into space. Whatever doesn't jump off is dissipated (wasted) as heat somewhere in the system. If too much is reflected back from the antenna and dissipated within in your transmitter, the transmitter overheats ($$$) or it reduces power to protect itself and nobody hears you.

A simple, inexpensive antenna that comes close to the ideal will probably work on only one band. For multiband operation you'd need several of them ($$$) and maybe need multiple poles. ($$$) ... or you could buy a multiband, combination antenna. ($$$)

The tuner is trickery to deal with the power that didn't jump off. It allows a compromise antenna -- one not perfectly suited for the intended purpose -- to be used without overheating the transmitter. (The transmitter must see a 50-ohm load to stay happy.) Changing the length of the feedline is another form of trickery to keep the transmitter happy, but it doesn't improve the antenna, either.

Tuners are very useful and not terribly expensive, which is what makes them so common in the shack.

I need to learn all
> about SWR and impedance in regards to Antennas, from start to finish.

Maybe, but only if you want to know the _why_ of antennas. You can buy and use lots of great ready-made ham things without understanding exactly how they work. [Example: My car has fuel injection and electronic ignition; I only sort of understand how they work and could NOT fix them if I had to. I don't need to.]

> Is there an easy-to-read tutorial out there for a beginner like me?

Somebody said The ARRL Antenna Manual. I agree. At first, you can pick and choose what to read. As you read more of it, a coherent picture should emerge. I hope you didn't ditch too much HS math.

I used a 7" magmount for a 5/8 WL on 2m.
It had a rubber boot.
I used it most days to and from work, which involved putting it on and
taking it off twice each day. And then there was other use.
Each time, before I put it on, I wiped the mounting spot (in the centre
of the roof) with a soft rag (with maybe a bit of spit if nobody was
looking).
Four years later, when I got rid of the car, the mounting spot was
extremely highly polished, which (being a company car) is more than you
could say for the rest it.

As I said earlier, there's a lot of misinformation floating around.

A high SWR doesn't mean there's "reflected energy" which is going to be dissipated anywhere, least of all in your transmitter. Except for transmission line loss (which admittedly will be greater, although usually insignificantly so, if the SWR is very high -- see the Antenna Book), all the power leaving the transmitter will arrive at your antenna. Thinking of waves of energy bouncing back and forth looking for somewhere to be dissipated will lead you down paths that you won't be able to reason your way out of. As has been clearly demonstrated on this newsgroup over and over. Read the Antenna Book and other good texts, and don't try to make up additional imaginary waves.

"Sal" is right about one thing, though. Most transmitters will reduce output power if the SWR gets too high, which tells the transmitter that the impedance it's seeing is beyond the range for which it's designed. (The problem is that various places in the transmitter can encounter voltages and/or currents too far above design values, or impedances which might cause instability. It's not because there are waves of "reflected energy" which dissipate themselves in the transmitter.) So you do want to keep the SWR measured at the transmitter below that value. There's no harm in having a very high SWR on the feedline, however, as long as it has low matched loss.

what does the voltage read when it is turned on? an rs-20a is probably not so old that caps would go bad, and the low voltage left over when you turn it off probably means the caps are holding a charge.

Maybe black, electrical tape on the bottom of the mag mount (applied to that mag mount, of course.) Would be thinner, but I suspect it might still cause some problems with increased capacitance. Count paint that mag mount base with liquid electrical tape, which I get at my local ACE Hardware store. But then, you could still get some grit underneath the mount. Saran Wrap? Very thin. Might be your best bet. Tough and flexible. Maybe that would help...

Good luck.

Dave

Interesting Ian,

I suppose the fact that you removed the antenna twice a day and wiped
the spot made a substantial difference. In my experience, I did not
remove the antenna daily, but as a lot of amateurs, I used the magnet
mount in lieu of punching a hole. After a year, the paint had
terrible scratches where the magnet had been placed. Nevertheless,
this still does not solve John's problem with the detuning he is
experincing when using a rubber boot or other protective device. What
John does not say, and I would like to know, is why he is unable to
retune the antenna to compensate for the change in capacitance. Will
the antenna not resonate? or is there some physical limitation, such

as the radiating element being too short, ect.

If he said "sometimes overheats", he would be correct.
An SWR of 10:1 certainly *can* cause an over-current condition
in an unprotected transmitter assuming the reflected current
is in phase with the forward current at the transmitter.

However, just as likely is that the reflected voltage is in
phase with the forward voltage at the transmitter and an
over-voltage condition *can* result in punch-through of the
final transistor.

If over-current and over-voltage were not a problem caused
by reflected waves, protection of the finals would not be
necessary.

Note that the impedance seen by the transmitter above is a
virtual impedance, not an impedor. Virtual impedances are
only a *result* and not the cause of anything. Virtual impedances
are not the *cause* of over-current or over-voltage conditions.

Anyone who scoffs at virtual opens and virtual shorts being
the *cause* of the re-reflection of reflected energy cannot,
without contradicting himself, turn around and argue that
the virtual impedance seen by a transmitter is the *cause* of
the mismatch. One cannot have it both ways.

My Larsen mag mount came with a thin sheet of
aluminum across the bottom. After much use, the
aluminum started to tear. I replaced the factory
aluminum with ordinary aluminum foil taped to the
base. It's not as sturdy as the original but it
costs virtually nothing to replace.

My Astron SS-30M has an adjustment screw on each meter face. Maybe the
needle just needs to be "zeroed" with no voltage applied. Or perhaps
you could check the reading with an external VOM?

The output voltage drops slowly when the unit is switched off. In
fact, I compared the voltage drop on the RS-20A to the voltage drop on
an RS-12A that I currently have in use. The voltage drop on the RS-20A
is much slower than on the RS-12A, and when the voltage has dropped
down to around 4 or 5 volts then it really slows to a snail's pace.

The RS-20A isn't metered. I'm measuring the output voltage with a
multimeter.

> the impedance it's seeing is beyond the range for which it's designed.

Not readily apparent is the contradiction between these two statements above which needs to be resolved. Reflected energy cannot exist without energy, i.e. without ExB watts. It is the energy in the reflected waves that is the *cause* of the impedance "seen" by the transmitter. There is *zero* dissipation in that virtual impedance so it is NOT a real resistor - it is a dissipationless resistance.

The impedance seen by the transmitter is not a resistor or inductor or capacitor, but instead is a *virtual* impedance *caused by* the magnitude and phase of the reflected wave with respect to the magnitude and phase of the forward wave. The impedance seen by the transmitter is:

Z = (Vfor+Vref)/(Ifor+Iref)

where the voltages and currents are phasors, each with a magnitude and associated phase. There is NO resistor! There is NO inductor! There is NO capacitor! There is no power dissipation! Virtual impedances cannot cause anything.

It is interesting to note that the very people who support the virtual impedance seen by a transmitter as being the cause of the conditions there are the same people who rail loud and long against a virtual short being able to cause 100% re-reflection. Why does a virtual impedance cause things to happen only at a transmitter but nowhere else?

If there's no "reflected energy", the transmitter will see the characteristic impedance of the transmission line, e.g. 50 ohms. So the transmitter CANNOT see any impedance other than Z0 unless reflected energy is the cause of the deviation away from Z0.

Depending upon the phase of the reflected energy, all
or some or none of the reflected energy may make its
way into the transmitter. The exact magnitude of
joules/sec making its way into the transmitter is:

P = P1 + P2 + 2*SQRT(P1*P2)cos(A)

where 'A' is the phase angle between the E-fields of
EMWave1 and EMwave2 and P1 = E1xB1 and P2 = E2xB2
The last term is known as the "interference term".
If it is negative, it represents destructive
interference. If it is positive, it represents constructive
interference. It should be obvious that 'P' above, can
assume any value between zero and a maximum value so
the amount of reflected energy flowing into the transmitter
can be anything from zero to that maximum value. If the
transmitter is looking into an ideal shorted 1/4WL stub,
the reflected energy flowing into the transmitter will
be zero just as the food-for-thought example demonstrates,
i.e. none of the available power is dissipated in the
transmitter. If the transmitter is looking into an ideal
open-circuit 1/4WL stub, all of the reflected energy will
flow into the transmitter, i.e. all of the available power
will be dissipated in the transmitter. How much depends
upon the relative magnitudes and phases of the forward
and reflected waves.

Consider drilling an NMO mount and get the Larsen whip for 27-30 MHz.

> continually trying to contradict it?

Not if all you do is trade one old-wives tale
for another. One cannot understand these concepts
without understanding the conditions that cause
EM waves to interact.

The conditions that cause interaction between EM
waves are coherency and collinearity (in the same
direction in a transmission line).

The interaction of reflected EM waves can result
in zero or maximum reflected power being dissipated
in the transmitter - and anything in between.

The interaction of reflected EM waves at a thin-
film coating on glass can result in zero or
maximum reflected energy and anything in between
depending upon the thickness of the thin-film.

Or if anything is externally connected to the power
supply, the left over low voltage can be coming from
that connected device. I have my RS-20 connected to
a deep discharge marine battery. If I forget to
disconnect the battery from the power supply when
I power down the supply, the meter on the supply
displays the battery voltage. I'm told that can
damage the regulator within the supply but that
has never happened to me.

No, nothing is connected to the supply when the measurement is made.

The power supply itself is humming. It's humming fairly loudly, louder
than my other Astron supply. Still, I'm less worried about that than
by the lingering voltage after shut down. I know the Astron's tend to
make a bit of noise.

A friend of mine wants to try out the AO program by Beazely.
The program is not in the commercial market now as it is not being
sold
He wants to make a copy of my disc to try something out that requires
AO
I suppose since it is not for sale which probably means copyrights are
now defunct
I don't see any reason to not acceed to his request.
Ofcourse so few people pay for computor programs these days but I like
to do things right,
after all if a patent is abandoned then it is a free for all since
the advance of science cannot be stopped and it becomes freeware

Dave (and John Doe), the idea is to incease capacitance. Large capacitance
is a solution to the problem not a cause of problems, agree?

Why not ask? If the author is not selling it, then he might well be quite happy for you to distribute a copy.

> after all if a patent is abandoned then it is a free for all since

I don't think the copyright expires on a bit of software like this. I belive there is a limit on books, but that is about 30 years or so - quite a long while anyway. Should software be the same, then I doubt the copyright has expired on any of it.

Steve,
Most power supplies with big transformers can hum. I had an Astron
RS-20A for years, and it always hummed. If the humming is really loud
then something may be wrong.

I'm assuming that when the supply is powered up, it is putting out
close to 13.5 to 13.8v. You may want to measure the supply ripple to
see if it is abnormal.

Regarding the voltage present at the output:
Did you check for the same behavior on your other supply?
You didn't say how long after you shut the supply off that you
measured the 1 volt at the output terminals. It is most likely the
huge capacitor has not had time to discharge. A bleeder resistor
accross the capacitor would probably shorten the discharge time. The
way to check is to open the supply, power it up for a minute, then
power it off. Monitor the voltage accross the capacitor. Discharge the
capacitor through a resistor (around 200 to 500 ohms) for several
minutes, then disconnect the resistor, and see if the voltage floats
back up. Some voltage on the capacitor would not be abnormal.
If the power supply operates normally when powered up and the ac
ripple voltage is low, then a bleeder resistor across the cap would
solve your problem.

Just use a very thin piece of plastic. Some companies that make mag-
mounts sell circular pieces with adhesive to stick to the antenna
base. But you can just cut out a disk from a zip-lock bag and put
underneath the magnet. It won't slip around.
The thicker the material, the more it affects the performance because
it reduces the capacitance to the metal that the antenna is placed on.
Thinner is better here.
By the way, someone told me to try felt years ago, and I did. The
antenna had more tendency to slip around, and it DID mar the paint on
my car, more than if I hadn't used anything.
Last comment: a balloon would probably get water in it, and keep the
antenna base wet for a long time after it rains (at least here in
Portland where I live!) Not a great idea. And balloons aren't known
for their tougness.

Yup,
you are probabl;y correct! I will get around it by lending it
while retaining ownership which apparently what is normaslly done
these days.
Shame that it is being squirreled away so nobody can use it
especially since it is still considered the best there is.
As for asking he does not answer Emails as he now works
in other areas. People have been asking for it so that they
can see and model Gaussian antennas for themselves and I don't know
of another program that would accept it

I've been a ham since '58, and did 26 years in the navy in various areas of communications and radar as an operator, technician, and manager. I have done my best to learn about antennas and have quite a body of knowledge accumulated, some of it good, some of it fallacious. Some of it remains a complete mystery to me. There are a great many misconceptions when it comes to antennas, feeders, SWR, and the like.

If I had paid attention to what some people say about SWR, conjugate matches, and the like I would still be hesitant about putting up an antenna. I'd still be looking for the perfect one.

Despite all the myths and misconceptions, many hams are surprised to find out that regardless of how bad their antennas may seem in theory, in practice they are getting out.

Put up an antenna, and 'tune' it for minimum SWR, then have fun. You will find years of fun ahead and they will give you the time required to learn more about antennas. Do not try to learn all there is -- you won't get there. Instead, try to learn where the fallacies lie and try to avoid them.

The hardest part is committing yourself to putting up an antenna which you know from theory is not perfect. Once you get it up and find that you can work the world with a few watts and a wet noodle, then you can take the time to learn, experiment, and find an antenna that meets most of your needs. Don't go looking for the perfect one -- it does not exist.

Just follow the thread of logic - The power supply
converts AC to DC. The transmitter converts DC to
RF which is routed to the antenna. :-)

I wasn't implying that you should cut the element. What I was trying
to understand/suggest, is whether the whip is too short already. Have
you checked the antenna with an analyzer? Is it resonate anywhere on
10?

Hello, Roy, and all. No disrespect intended to my fellow hams but some posts on this ng begin with something about antennas or related devices and stray off to neverland. I think we should be discussing classic and novel antenna designs appropos to ham radio (especially ones that don't require violating electromagnetic theory to operate ;-). To those that want to discuss the theoretical aspects of electromagnetics there are appropriate usenet venues (e.g. sci.physics.electromagnetics) for that purpose.

There seem to be a few folks out there these days that think some unknown principle(s) in electromagnetics has gone undiscovered (think CFA). Electromagnetics is a mature science (theory is well characterized mathematically and validated through experiment.) It is up to those making these "new" claims to provide the experimental evidence (especially if the applied mathematics appear to be violated). My .02 worth. Sincerely, and 73s from N4GGO,

==========
Steve , The above indicates that the electrolytic cap or caps seem to be
OK. That the output voltage on the RS-12A declines faster is that its
electrolytic cap(s) highly likely have a lower capacity value and hence
store less charge.

I do have a RS-50A (not in use) capable of delivering 13.8 V-50 Amperes
, although the terminal connectors look like only good to pass up to 20
Amperes.
There was a sticker showing input voltage 220 V but when removing it,it
shows 115 V The primary winding of the transformer must be
two times 115V. The unit works but hums heavily (the transformer sits
close to the metal enclosure).
I fear that the USA made unit is actually designed for the US power
frequency being 60 Hz ,whereas here in Europe we have 50 Hz.
For large transformers it can be unacceptable to run a unit designed for
60 Hz ,on 50Hz.
When time permits I'll have a closer look.
I would like to sell it in the USA where I shall be shortly for 2 months
,but the unit's weight is prohibitive, (19 kg or 42 lbs) to bring it as
air luggage .

I wasn't going to get into these since ceramic was not a material of choice in this discussion. But yes, the highly doped Z5U's will give you a high C and low temp stability (and high "other" coefficients) while an NP0 pure ceramic will give you just the opposite (you will have one heck of a stable capacitor).

None of these dielectrics are immune to humidity absorption. They must all use a good non-hygroscopic outer casing material. The ability to withstand high humidity is not such much a property of the capacitor material as it is a property of the package that it comes in.

>Many capacitors, depending largely on the dielectric, also have nonlinear

>consideration,

Usually, these considerations are most important when choosing large bulk or filter capacitors for inverter and power supply circuits. Who cares about the loss tangent of an EMC ceramic Y cap or a high frequency ceramic bypass cap? Or, for the "balloon" cap in question? For common capacitor materials typically used in those applications, they will not generally matter. But in the same sentence as "loss tangent" and "ESR", why use "power factor"? Would it be better tio say "dissipation factor" which emphasizes the ohmic loss rather than the reactice power characteristic?

Yes, we do not need to worry about the loss tangent, the dielectric contant, the dielectric strength, the ESR or the temperature coefficient of the balloon. This solution is rather over-engineered ;-))

Don't know exactly to whom you are referring but my
position is not new and relies upon simple physics
that has been understood for a century, at least in
the field of optics.

For some reason, most posters to this newsgroup
are ignorant of EM wave cancellation due to interaction
between two coherent collinear waves.

I have posted a graphic at:

http:www.w5dxp.com/thinfilm.gif

It has been 48 hours since I posted it and none of
the newsgroup gurus have answered the question: What
happens to the reflections toward the source between
t2 and t4 when the first internal reflection arrives?
It's a simple question. One wonders, why the complete
lack of any technical response. Seems the only responses
to this posting will be ad hominem, as usual.

> 73s from N4GGO,

Aha. Maybe you can answer this question: Do you agree that a series of
ground radials for a vertical antenna is a true "ground" in the sense that a
1/4 wave antenna radiator is "grounded"? Or do you believe that the only
true ground for a 1/4 wave antenna radiator is true earth ground (or as
close to that as you can get).

I vote that the radial system is nothing more than a tuned counterpoise.
Only a true earth ground produces the mathematical "image" from the other
"half" of the 1/4 wave antenna for any frequency. The radial system actually
radiates as an antenna element and that gives the perception that the radial
system is acting as true "ground" (but only at a specific frequency).

This should be a simple, classic antenna question of the type you suggest
for this ng, e.g. settled science, yet no one seems to have a definitive

answer.

A copyright doesn't go "defunct" because the author ceases selling the copyrighted material. In fact, the author doesn't need to sell the material at all in the first place, or be alive for that matter, for the copyright to be in effect. And the copyright exists as soon as the material is created. Anyone truly interested in learning what the (U.S.) rules really are can find ample information at http://uspto.gov. I do realize, however, that some people would rather make up imaginary rules to justify what they want to do anyway.

I'm happy to say that a lot of people do pay for software these days. It's not uncommon for me to get a check from an EZNEC user with a request to send a program to a friend. It's refreshing and heartening to see that most people are honest, and see the fairness of paying for someone else's labor.

If you gave a technically relevant argument, Cecil, you might
get a technical answer in reply. Actually, the reason you have
trouble getting people to argue with you is that everyone with even
half a brain has already plonked you. Anyway, Tom (the intelligent Tom)
had it right: it can all be explained neatly by superposition. There's
no reason to make up any crackpot theories, or magical, mystical
stories. It was all understood long before you were born.

Let me take a crack at it.

Consider the path of reflections inside the thin film to be a tramsmission
line.

1. If at t1, amplitude is high, then at t2 amplitude is 0.

2. from t2 to t3 we are going from from 0 to high,

3. from t3 to t4 we go back to 0.

So in this case where n is odd, photons exist. Where n is even, photons doe
not exist. They are absent at low points on the thin film transmission line
while they are presnt on the outer surface of the thin film happens or high
points. Energy in this part of the cycle is distributed such the energy is
reflected toward the source while only the original incident 0.9801 w
transmits into the glass.

When amplitude at t1=0, the opposite occurs. 0.9801w still transmits through the glass along with the reflections.

Thus the locations of reflected photons on either side of the thin film redistribute in accordance with the frequency of the source and the thickness of the thin film.

I know this is screwed up but I thought I would at least give it a try.

Just pondering.. Another thing that bothers me about the mobile dipole
theory is that the body element is not resonant in most cases, and
thus
should not act as a decent working dipole leg in those cases.
Now if you by chance had a vehicle with the whip mounted at the rear,
and the front vehicle length by luck happened to be resonant, then
yes,
I could see much more of a dipole effect.
But say with the typical low band HF mobile, the car is not even close
to be capable of being a resonant element.
So I'm also tending to believe it acts more like a typical short
vertical
that is mounted on a varied size sheet of metal, but also coupling
with
the earth.
The coupling to earth can be verified by driving over certain types
of
ground, highways with rebar, etc.. Some areas are noticeably better
than others.

One may or may not wish to differentiate between truth and simulation
provided the effect is the same. I understand your point. It is sort of like
the difference between one who memorizes formulas and one who understands
them and can derive additional formulas.

Perhaps the reason, Cecil, is because it's too simple. Perhaps it's BORING. Perhaps it's beating a dead horse. You're welcome to call it "interaction" if you wish; you're welcome to make it out to be more complex than it needs to be. But don't be expecting me to be using the word "interaction" for the case of simple vector addition in a linear system.

I had this same conversation with Dr. Best years ago. He
said that the canceled waves continued to travel in a
straight line with zero associated energy. It sounds
to me like you support that same notion. If not, please
explain your position.

Undetectable phantom waves containing zero energy are
NOT simple. They are absolutely magical. How can waves
exist without energy?

Actually Tom, waves that are not canceled and continue
to exist forever without energy is the magical side
of the argument. My side of the argument says that
waves whose energy goes in some direction other than
the original direction have ceased to exist. Would
you please explain how your non-canceled waves
continue to exist without energy?

I already have two copies which are paid for so I can
share one with another person or give it as a gift
Seems wierd to me that a patent costs a lot of money to get
and requires a maintenance fee every two years to provide
protection in the name of science as well as forcing
publication for public reading Yet a computor program
has similar protection as a trade secret or better which lasts for
an awefull long time and can be used for the prevention
of the advance of science by not making it available so
the science can be advanced.
I think the public is realising that the feds are incompetant and the
law requires extensive costs to the owners with little chance of
returns.
I see it done in the musical industry and there are plenty of places
on
the net that furnish "abandoned" computor programs. We have plenty
of laws in the U.S. but the feds are not interested in enforcement
anymore.
Judges also are not willing to get involved with such nuisance cases
either
since damages are not being proven as extensive and the rights of
"fair use" laws
are making things both difficult and costly. The entertainment
industry has
very deep pockets but are finding that that is not enough since it
is
now considered a "scoff" law. A patent holder knows first hand that
it is nigh impossible to stop piracy unless the pockets are really
deep and
big profits and competition is at stake.

I was trying to get some comparative data on quad vs quagi antennas for a club presentation. I would like to be able to compare Quads of a given number of elements with Quagis of the same number. It is my understanding that for short boomed antennas the quad will win out but the quagi is best for longer higher gain antennas. Some numbers would really help illustrate this but so far I have not found any information on short quagis.

What a novel but insane idea!
Ham radio today has determined that all is known about antennas and wo
betide
any body who tries to venture forward with some thing new. If
something new
is to be able to penetrate these barriers he must have commercial or
collegate
ties other wise they will be battered into the ground by hams. There
are very few people if any
in ham radio today who have the necessary mathematical skills to
review solid presentations
or the willingnes to subject himself to members of ham radio as it has
now dropped down to.
Read QST regarding mobile antennas of today and save it because the

comming
issues certainly will not improve on it and they certainly are not
interested in
antennas where all is already known.

What is it about these waves that is creating problems with antennas?
Are the problems specific to the southwest desert area and what
advancement
are you looking for when the discussion is resolved. Frankly, until
what constitute a" wave" which has three degrees of freedom is
defined
with respect to radio as well as its impact on communication, any
foray
into quantum mechanics would appear to be one of diminishing returns.
Unless ofcourse you are intending to write a follow up on
"Reflections"
and start the discussion about "standing waves" where old discussions
can be reprinted over and over again.
Nothing personal since you often present new ideas that are enjoyable
to read
even tho you still get hammered but the "wave" thing went out with the
tide a long time ago
and memories have grown dim as to what it is all about
Best regards

It was a joke. I actually tried it on my wifes car, she wouldnt let me
drill a hole. The antenna stayed on about 3 minutes, just long enough
for her to get out of the neighborhood and get up to about 45MPH, then
it slid off and scratched the side of her car.Slipperiness is a BIG
disadvantage.

It's hardly an old wives' tale.

I mistakenly put a 2m antenna on my dual band HT and tried to use it for a short QSO on a nearby 440 repeater. The other ham said I was barely making the repeater, while my poor HT got so hot that I could barely hold it after a minute's use.

The antenna was wrong and the heat was real -- whatever the theory behind it.

Hi Sal,

A recurring theme here is the myth that all the energy in reflected waves on a transmission line from a mismatched antenna is carried all the way back to the transmitter and necessarily dissipated as heat which is likely to damage the PA.

It is no doubt an appealling explanation of why a PA may run hotter under some circumstances, but it does not explain why for instance under some circumstances, a PA may run cooler on a mismatched load.

Being appealing does not imply correctness of the explanation.

I will sit down now, and await the inevitable stream of anecodotal evidence that doesn't and cannot support the generality of the statement.

Owen

Let the anecodotes flow...

Your FM HT is a classic case than can be adequately represented by a steady state analysis. Your HT was operating into a load that increased its dissipation, but there would be almost certainly be other mismatched loads that would decrease its dissipation... but you wouldn't notice the event, you would likely only remember the times the HT was too hot to handle.

I await the inevitable photon explanation.

It's a shame there is not a law that allows software to be used freely
after x years of no new updates.

I recall reading that some people have bought Cray supercomputers for
use at home as a hobbiest. But apparently the software to run them is
specific to the S/N of the machine, and you can't get it without paying
huge amounts of money. Seems a bit odd if the machine is 10 or more

years old. There is no commercial loss to a company if someone hobbyiest is running an old machine that is less powerful than his PC.

I know Sun Microsystems have been helpful in supplying old software (SunOs + others) to people that want to use it on old machines. But Cray were not apparently. And from what I understand, its not as easy to copy on a Cray.

You are welcome to lobby your represntatives to change the copyright
laws.

> I know Sun Microsystems have been helpful in supplying old software
> (SunOs + others) to people that want to use it on old machines. But Cray
> were not apparently. And from what I understand, its not as easy to copy
> on a Cray.

There are two things wrong with this.

1. Sun has not been helpful supplying SUNOS for old machines, they have
only been less than agressive in enforcing their copyright.
However you will find that the sites that they have not gone
after are outside the U.S.

They will provide for free download Solaris (SUNOS 5) 8, 9 and 10
for download if you sign up (for free) and accept their restricted
license.

There is an open source version of Solaris 10, however that only supports
the UltraSparc II and later processors.

Solaris 7, which was available for shipping costs, was originaly released
at about $500 and derivative versions (e.g. Tadpole's) were never free.

Anything older is long gone, and not available from SUN.

2. What's left of Cray is owned by Sun. After Seymor Cray died, the
company went under and Sun bought them out. SUN produced a line
of "Cray" computers which had SPARC processors in them.

Note that many UNIX vendors had a license from AT&T that required
them to pay AT&T $60 for each workstation (2 or less users) or
$250 per server binary package they sold.

Sun in those days included a RTU "right to use" license for SunOS
when you bought a new computer, but technicaly it was not transferable.

The transmitter gets hot because it is operating into an incorrect load impedance, not the 50-ohm load for which it was designed. As far as the transmitter is concerned, that is the only problem.

What caused that incorrect load impedance is a totally different topic.

If you measured the impedance of that incorrect antenna, and then replaced the antenna with a dummy load of the same impedance (a resistor of the correct value, in series with an inductor/capacitor of the correct value) then your transmitter will not know the difference. The same value of load impedance will cause it to behave in exactly the same way.

There are many different physical types of loads that could present exactly the same impedance to the transmitter. These include antennas, dummy loads and various combinations, with or without some length of transmission line involved. So long as the load impedance presented to the transmitter is exactly the same in all cases, the transmitter behaves exactly the same (once it has reached steady state, after the first few cycles of RF... more about that later).

The amount of power that the transmitter can deliver into that incorrect load will depend on the transmitter circuit and on the value of the load impedance - but NOT on the physical type of load.

You can measure the impedance of the load by disconnecting it from the transmitter and connecting it to an impedance meter. (Seems obvious?

Think again - every time you make an impedance measurement, you are using the principle that impedances of the same value are interchangeable with no effect on steady-state operation.) If the load happens to be an antenna and transmission line, you can use programs like NEC and established transmission line theory to make an accurate prediction of the load impedance. If the system happens to include an ATU, that is just another device that modifies the load impedance presented to the transmitter.

At that point, you're finished with antennas, transmission lines and ATUs - once you know the load impedance they present to the transmitter, everything else depends on the transmitter alone.

In other words, the antenna/transmission-line/ATU system can - and wherever possible, SHOULD - be cleanly separated from transmitter design. The separation interface is the output connector at the rear of the transmitter.

In the huge majority of applications, both amateur and professional, it IS possible to separate those two topics cleanly and completely. It seems perverse to tangle them together unnecessarily.

All the above refers to the steady state, where the signal level is constant; and if a transmission line is involved, the pattern of standing waves is established and unchanging. For completeness, we now need to check if anything was different during the few moments after switch-on, while the steady-state pattern of standing waves was becoming established. Starting from switch-on, we need to look at each of the successive reflections and re-reflections along the transmission line, and see how the steady state came to be.

The first thing to notice is that with the types of signals and lengths of transmission line that we amateurs use, the steady state is established within the first few cycles of RF, ie it all happens over timescales much shorter than the signal's own envelope rise/decay time. This means it is 'nice to know', but will seldom be of practical importance.

A detailed analysis of the buildup of reflections along a transmission line will be forced to consider reflections at the transmitter as well as at the load - in other words, we have to specify a reflection coefficient at *both* ends of the line. Chipman's book [1] gives a very detailed analysis of this, and shows how the addition of voltages over multiple reflections gives rise to a standing wave. The amplitude of the standing wave builds up as mathematical series, in which each successive reflection and re-reflection contribute an additional term. Some terms add to the total while others subtract, and each successive term makes a smaller contribution than the one before, so the series will converge towards a constant value which represents the steady state. It should be absolutely no surprise that, when summed to an infinite number of terms, this series produces exactly the same results as the steady-state model - exactly the same pattern of standing waves, and exactly the same load

impedance presented to the transmitter.

The important conclusion from this more detailed time-dependent analysis is that re-reflections at the transmitter have NO effect on the final steady-state pattern of standing waves. The ONLY effect of re-reflections at the transmitter end was on the time-dependent details of how that pattern built up, and on the final steady-state signal levels. The magnitude of the standing waves depends on the transmitter characteristics (in other words, on the 'signal level') but the shape of the standing waves and their location along the transmission line depends only on the line and the load. There are no special cases here: the same conclusion holds for all values of reflection coefficient at the transmitter end, including 1 and 0.

Thus, even a detailed time-dependent analysis confirms that, once we have reached the steady state, we can indeed make a clean separation between the transmitter and its load. And since we can, we should.

As always, Ian has done a much better job than I could have, so there's not much point in trying to repeat what he said.

But I did write up a lengthy essay several years ago, in response to the same insistent rantings about reflecting waves of average power that's still going on in this newsgroup, and it has some numerical examples with a very simple circuit which illustrate the problems with what you said. You can get it at http://eznec.com/misc/Food_for_thought.pdf. A little past half way down is "Food for thought: Forward and reverse power". If you're not interested in the math, scroll down a few paragraphs from there to the table in Courier font. It and the text below explain how it shows where the source dissipation is higher, lower, and about the same when the load is matched, for three different loads all having the same "reverse power". Another entry in the table is an example where the "reverse power" equals the forward power (an infinite SWR) yet the source dissipation is zero. People who believe that "reflected power" ends up heating up the transmitter should take a careful look at this, and see if they can explain it.

The established transmission line theory that's been well established for over a century and that Ian, I, and countless others use daily for solving real problems will, as shown in the example, tell us exactly how much power is where and why. The "power is absorbed in the load" folks can point to transmitters that get warm (sometimes) when working into (some) mismatches. But they can never come up with a coherent reason for the results shown in the essay table, or equations which will predict just how much "reflected power" a transmitter will absorb and when. And the reason is just as Ian said.

Unfortunately, some people, when presented clear evidence that the concept is wrong, cling desperately to it nonetheless. For those, explanations and evidence are a waste of time. But hopefully there are a few readers out there who will see the problems in resolving their theory with the evidence and redirect their thinking.

Once a black cat walked across the street in front of me. I had a wonderful day! The wonderful day was real, whatever the theory behind it. My basis for crediting the cat is just as valid as yours for crediting "reflected energy" for the heating. And based on similar logic.

Jimmie, this is not a flame:
But, you intend to lecture to others and you do not even begin to
understand the subject - do you see a contradiction here?

There is no way this group can turn you into an instant expert by way
of one or two postings to this reflector... The possibilities of you
looking like an idiot in front of your friends are endless - all it
takes is one question from the audience where you try to wing the
answer, then someone points out the holes in your answer, and poof!

My best advice is for you to cancel your lecture and begin a bit of
testing on your own (become an expert)... Two meters is an easy band
to work with... Get a wood handle for a hoe, or some such, and drill
holes... Start with a yagi from the antenna hand book - let me suggest
3 elements to start with, and if you want more gain then go to 5 or 7
elements, i.e. always have an odd number of elements... Measure the
gain and the pattern at 0-45-90-135-180 degrees...
Then change the reflector to a quad element - repeat...
Then the driven, etc...

Then when you give the lecture you will know the material, you will be
able to show them the antenna(s), and your test data... And even if
you didn't get the answers you/they expect, you will be the local
expert...
cheers ... denny / k8do

Tom Donaly wrote:
> ... it can all be explained neatly by superposition. There's
> no reason to make up any crackpot theories, or magical, mystical
> stories. It was all understood long before you were born.

No one is making up "crackpot theories or magical
mystical stories". I am reporting the laws of physics
by physicists who understood them before the first man-
made RF antenna or transmission line ever existed. Some
people on this newsgroup are trying to sweep those laws
of optical physics under the rug and ignore them. I am
merely attempting to lift the rug and expose what has
been known since long before you were born.

What happens to the ExH joules/sec in two coherent
collinear EM waves that are superposed such that the
resultant wave contains ExH=0 joules/sec forever in
the original direction of travel? None of you "experts"
have ever answered that question. You guys have tried
your best to completely ignore the fact of physics that
EM waves contain energy and cannot exist without energy.
Some of you have gone so far as to assert that reflected
waves exist without energy and just slosh around in
violation of the laws of physics for EM waves. There is
your magical, mystical story but it is not coming from me.

The advice from the gurus here is to use the voltages in
the waves and completely ignore the necessary energy in
the waves along with the conservation of energy principle.
Ignore things that you can see with your own eyes? Now
that is your "crackpot theory".

Optical physicists who do not have the crutch of voltage
upon which to lean, understood the energy content of EM
waves a century ago. All they could measure was the
power density and as a result, the field of optics
understands EM waves while the field of RF remains
ignorant of such. As a result, we are fed old wives'
tales about reflected waves containing zero energy
and just "sloshing" around when there is nothing to
cause them to slosh.

You implied that reflected energy is always dissipated
in the transmitter.

How much of the reflected energy is dissipated in the
source depends upon the interference pattern at the
source. As w7el points out, dissipation in a voltage
source can be reduced to zero by the astute choice of
a special best case of complete constructive
interference in the direction of the load.

>>> continually trying to contradict it?
>> Not if all you do is trade one old-wives tale
>> for another.
>
> It's hardly an old wives' tale.

1. The original old wives tale is that reflected power
always causes the source dissipation to increase,
even when it is a voltage source.

2. The subsequent old wives tale is that reflected
energy always ends up being radiated by the antenna.

Examples of decreased dissipation in the voltage source
in the presence of reflections proves #1 wrong.

Examples of increased dissipation in a current source
in the presence of identical reflections above proves
#2 wrong.

The power density in reflected waves is proportional to
ErefxHref and *CANNOT* be zero. Where that energy goes
obeys the conservation of energy principle. Anyone who
says all energy winds up being radiated by the antenna
is simply ignorant even if portraying himself as a guru.

Owen Duffy wrote:
> It is no doubt an appealling explanation of why a PA may run hotter under
> some circumstances, but it does not explain why for instance under some
> circumstances, a PA may run cooler on a mismatched load.

What does explain it is the amount of destructive vs
constructive interference occurring at the source.
Assuming an unprotected source:

If the constructive interference is toward the
load, the source dissipation will decrease. If the
constructive interference is toward the source,
the source dissipation will increase. The conservation
of energy principle really does work to conserve the
ExH energy in a reflected wave.

Just because a special case results in zero dissipation
in a voltage source does not give us the permission
to make a magical leap of faith to "reflected power
doesn't exist" or "reflected power is *always*
dissipated in the load".

If the constructive interference is toward the source,
it will run warm. If the constructive interference is
toward the antenna, the source will run cool. Antenna
tuners cause total destructive interference toward
the source and total constructive interference toward
the load. RF energy obeys the conservation of energy
principle.

> I await the inevitable photon explanation.

None needed. Interference patterns work for voltages and
that's all one needs to figure out why the source is too
hot or cool. It's a no-brainer. If the energy is going
into the antenna and not being reflected, that energy
is not being dissipated in the source. If the energy is
not going into the antenna, it doesn't take a rocket
scientist to figure out where it must be going.

I had read the points you make above in the antenna books... but did
not realize exactly how variable the effects are especially for the
cases where the elements are physically close. The examples in the
ARRL Antenna book are particularly heinous: they show elements
separated by a fraction of an inch (e.g. the twin-lead example, the
picture that shows the wires hanging from egg insulators) and these
examples are - from my experiments - the least likely to work at all.

> The interaction decreases rapidly as you spread the dipoles apart. If
> you can get them around 30 degrees apart, the interaction is minimal and
> you can just about treat them like separate dipoles. A lot of
> installations fall between these extremes, so the dipoles have some
> interaction but it's not as severe as it is when they're very closely
> spaced.

This is a very fundamental piece of wisdom, and a piece that deserves
more attention in the ARRL Antenna books. The current statement - "The
separation between the dipoles for the various frequencies does not
seem to be especially critical" is incredibly wrong for the close-
spaced exampls shown in the book.

I don't know, but if that's the case, than a thinner medium between the mag
mount and the roof would have a higher capacitance than a thicker one, like
felt. Or it least I think it would... If so, than Saran Wrap might be the
answer.

It is true that transmitters are dumb as a stump. However,
a human being should be smart enough to realize that the
virtual impedance, which is only a voltage to current ratio
has been replaced by an impedor with a resistor, inductor,
and/or capacitor.

The impedor *causes* the load conditions. That virtual voltage
to current ratio is a *result* and not the cause of anything.
To get down to the actual cause of the conditions, the human
being needs to know whether the load impedance is virtual or
not.

Why do you imply that a virtual impedance can *cause* the
conditions seen by a source but deny that a virtual impedance
can *cause* 100% re-reflection? Seems a contradiction.
In fact, virtual impedances cannot cause anything. The
voltage to current ratio associated with a virtual impedance
is a *result* of something physical. Choosing to ignore that
physical "something else" cause has gotten lots of folks into
logical trouble.

> In the huge majority of applications, both amateur and professional, it
> IS possible to separate those two topics cleanly and completely. It
> seems perverse to tangle them together unnecessarily.

It seems perverse to say the antenna system can be replaced
by a resistor and inductor or capacitor and nothing changes.
How about the radiation pattern? Does that change?

> It should be
> absolutely no surprise that, when summed to an infinite number of terms,
> this series produces exactly the same results as the steady-state model
> - exactly the same pattern of standing waves, and exactly the same load
> impedance presented to the transmitter.

How about the total energy in the steady-state system? The
number of joules pumped into the system during the transient
state is *exactly* the amount required to support the forward
and reflected power readings.

> The important conclusion from this more detailed time-dependent analysis
> is that re-reflections at the transmitter have NO effect on the final
> steady-state pattern of standing waves.

This is based on a rather glaring rule-of-thumb assumption,
that any standing wave energy dissipated in the source was
never sourced to begin with. Born of necessity, that is a
rather rash assumption. Thus some people sweep the reflected
energy dissipated in the source under the rug and forget
about it, hoping that nobody ever lifts the rug and points
out the conservation of energy principle.

>> I await the inevitable photon explanation.
>>
> None needed. If anyone wishes to introduce additional complications

> But when invited to join in, everyone else is at liberty to decline.

Optical physicists did not have the
luxury of dealing with voltages. As a result of dealing with
power densities, they learned a lot more than RF engineers
know to this very day. Optical physicists have never asserted
that reflected waves are devoid of ExB joules/sec or that
EM waves are capable of "sloshing around".

>From a optical physicists stand point I can understand
your dilema but I still don't understand how it applies to antennas,
what problems it creats and how can we fix it.
Obviously there are very few people in ham radio, unless there are
walk overs from CB, who are sufficiently educated in your field and
would be very unlikely to delve into the mysteries of same unless
they could see the future, or want to combat the problems shown
today. A case in point is the wave versus particle theory, and it
is just a theory.I have found that there is little or no interest
in that at all in ham radio as it is a hobby and thus the notion
holds true that all is known. Fortunately there is a world of
science out there that pursue science for its interest regardless
where it leads but hams view the hobby of radio as a means to talk,
endlessly in some cases, about things that are already known and
to defend such notions. Thus the presence of somebody who wants
to delve into the unknown properties of radio communication is
obviously on the other side of the fence as ham radio goes.
Yes, I am like you who does not believe that all is known tho
lacking in education in the field that you are in. But the days
have gone where ham radio was populated by those interested in
science and/or do not posses the powers of logic required.
Frankly this newsgroup is for regurguration only and to argue
not about the pursuit of science but as a means to spend your
time in retirement, a fact that is reflected often in the
form of senior moments that occur so often.
Cecil, we can't win for losing if success can not be recognised
by ignorance. Your only avenue is to write a book that people
will then use as a datum and regurgitate "facts" that you
provide. That is the only way with respect to ham radio can
you project your self as an "expert", remember what is written
and be consistent with the responses given and jeer at those
who will not concurr
Best regards

I have taken a careful look and have explained it using the
principles of destructive vs constructive interference between
EM waves adopted from the field of optical physics. Power density
in any EM wave is proportional to ExB and that includes reflected
waves in a transmission line. Your attempt to ignore the technical
facts about the necessity for energy content in reflected waves is
pretty obvious.

> But they can never come up with a coherent reason for
> the results shown in the essay table, or equations which will predict
> just how much "reflected power" a transmitter will absorb and when. And

It is untrue that those coherent reasons do not exist. I have
pointed out those "reasons and results from the field of optical
physics and you have simply chosen to sweep them under a rug.

> Unfortunately, some people, when presented clear evidence that the
> concept is wrong, cling desperately to it nonetheless.

Unfortunately, some people, when presented with clear evidence
that everything is explained perfectly by interference phenomena
and the conservation of energy principle, cling desperately to
"sloshing" EM waves and reflected EM waves devoid of any energy
content - something to do with motes and beams.

One can mentally install a one-wavelength piece of lossless
transmission line between the source and load which will
allow one to analyze the interference patterns. Constructive
interference toward the source certainly can cause heating
of the source in perfect accordance with the conservation
of energy principle.

Unfortunately, all it proves is that reflected power
doesn't always cause heating of the source. It does
not prove that reflected power never causes heating
of the source but that seems to be what w7el would
have us believe that he has proven.

If constructive interference between reflected waves
is in the direction of the load, the source will run
cool and the load will run hot. An antenna tuner can
accomplish that configuration.

If constructive interference energy flows unimpeded
backwards into the source without being re-reflected,
the source will run hot and the load will run cool.

This is no-brainer conservation of energy stuff.
Simply calculate the total number of joules contained
in the closed system and observe where those joules go.
Hint: the total number of joules contained in the
system are *exactly* the number of joules needed to
support the joules/sec in the forward and reflected
power readings.

EM waves obey the same rules, no matter what the
frequency. Some people would have us believe that
RF waves don't obey the same rules as light waves,
that the ability to measure the voltage associated
with an EM wave somehow changes its nature - that
RF waves are capable of sloshing back and forth in
a transmission line at sub-light speeds - that some
RF waves are completely devoid of an ExH power density.

After you have read the books try some thing different.
Obtain insulated wire and double it over itself to form a single
wire combination. Wind a considerable length on a former.
Using a MFJ analyser run thru the frequencies until you obtain a
resonance
at a reasonable impedance level and then scale for your desired
frequency.
Of course you must connect the MFJ to the two wire ends.

If you don't succeed first time around then short the wires in
increments
till you succeed.Wires close together can be turned into advantage if
you
go along with mother nature!
To make things easier, heat the insulation on the wire and insert
small needles
so you can hook up the MFJ at different turn lengths.
Be a leader not a follower

You make a good point. Many scientists have tried to connect
chemical, electrical and mechanical laws into one since all possess
a quantised measure of energy. But this can be very difficult
if one believes that a electron can behave both as a particle and a
wave
when the definition of both of these words are not chiselled in stone.
Read "Secrets of the atom", a new unified field theory,
by Dr Weldon Vlasak for some new analysis of the day.
Should be of interest to you as it evolves around shell
energy as in electricity no less

>as you can get).

If you are writing about the buried radials typically used by commercial AM broadcast stations, then they provide a much better "ground" in terms of conductivity than the earth itself. Without those buried radials, r-f losses in the earth within ~1/2-wavelength of the vertical greatly reduce the radiated fields it will produce, as those losses are in series with the r-f current flowing on the vertical.

>The radial system actually radiates as an antenna element and that gives
>the perception that the radial system is acting
>as true "ground" (but only at a specific frequency.

Whether buried or elevated, r-f currents flow in opposite directions on opposing pairs of radials. So if all such pairs of radials are installed orthogonal to the vertical radiator, the useful far-field radiation from the radials themselves essentially is zero.

>it.

In the explanations that hammered you for your naivete, there was no support of what was obvious to you, and perfectly acceptable as a true portion of a complete description. You testified to the experience of observing more heat where odds would have had you as likely testifying to the experience of observing less heat. We get none of those "less heat" reports because they naturally go unobserved. This is simply the common response to a psychomotor lesson instructed from Mom who I am sure warned you to "never stick your hand in the oven" but probably never uttered "never stick your hand in the ice-box." The first bears warning for its obvious consequences, the second hardly demands mentioning where its consequence is far less dramatic.

So we have these dramas over heat and the stage is filled with tenors crying their lungs out about the evils of misunderstandings (the last act of "Romeo and Juliet" comes to mind).

We should also first establish that your HT also exhibits waste heat. As no common transmitter of notable power is 100% efficient, it is raising its heat content in relation to its surroundings. If your hand temperature is cooler than that case surface, you note heating; contrariwise, if your hand temperature is warmer than that surface, you note cooling. As almost every item within reach of you is at room temperature and you rarely note it as cooler, it is hardly worth mentioning.

Your's was a sin of omission and what "you said wrong" was more in that neglect of mentioning all the cooling experiences in your life when your HT was mismatched. Of all the web pages, treatises, papers, tomes, chapters and verses dedicated to eradicating the myth of reflected power, all of them are equally sinful in their omissions. You are not alone there in Reflected Power Hell.

Let's begin first with "reflected power." It is in fact reflected energy that is noteworthy here, power is merely the manifestation of energy at a load. With this discussion of the HT and an antenna, there are two loads (and this raises the tenor's volume of agony another octave - I will leave that Operetta for other discussion).

The HT as a load is already exhibiting waste heat. Everyone's experience of operating one for several minutes will testify to that (yes, more anecdotal evidence) even when it is pushing energy into a matched load. Let's take the experience of your mismatch and put that antenna on a variable transmission line (one of those bench top tools, aka the "Sliding Load," few here have had experience with) and run the line through 360ï¿½ of variation as noted at the source (your HT). This study will fill in all those omissions from those publications so cleverly painted up and distributed across the web as sage advice.

When that returned energy meets the source energy and combines at the source, there are 360ï¿½ of variation possible outcomes. This combination can be in series aiding, in series opposition, or in all points in between. This will be a function of the length of the variable line. You add two aiding energies to the same load and it

will raise its temperature against waste heat. You add two opposing energies to the same load and it will subdue its temperature against waste heat. These are the extreme outcomes that fall 180ï¿½ apart based on the length of that variable transmission line. One outcome burns your hand, as you've already noted, the other does not (and you neglected to inform us of all those occasions you naughty boy!). All the combinations in between were by relation, inconsequential, and passed unnoticed (even more sins of omission).

Hence, the problem of anecdotal evidence is that it does not report fully. However, applying the label "anecdotal" does not automatically invalidate the observer's credible but isolated reporting; it merely demands a fuller examination. Unfortunately, you were denied this full examination in the criticism of your true observation. You observed one data point and perhaps were guilty of expanding it to describe a general condition = reflected power always heats a source. In fact, reflected energy can heat or cool a source in relation to its existing waste heat. The degree of heating or cooling is found in the magnitude of the mismatch, and the number of degrees that separate the load and the source.

As for all the side comments about how "reflections" do not contain (fill in the blank) _____; and that these issues are instead answered by Impedance relationships instead - Baloney cut thick. Reflections AND Impedance relationships occupy opposite sides of the same coin and are equally applicable. This concept of mutuality is so ingrained in the catechism of RF as to taint anyone who denies one explanation for the sake of the other as evidence of some special circumstance. In this regard, you were sinned against in kind. ;-)

>The impedor *causes* the load conditions. That virtual voltage
>to current ratio is a *result* and not the cause of anything.

At the terminals of the load, both the voltage and current are physically real and physically measurable, as also is the phase angle between them. Their ratio is the (complex) load impedance as seen by the transmitter.

Any device that creates those same electrical conditions possesses the same impedance; by definition.

The transmitter affects the magnitude of the voltage and current in the load, but it categorically does NOT affect their ratio, or the phase angle. In other words, the transmitter has no effect on the value of the impedance that is connected to it as a load, That value is created exclusively by the load.

>To get down to the actual cause of the conditions, the human
>being needs to know whether the load impedance is virtual or
>not.
>

I can see your underlying point, about the difference between a lumped impedance physically present at the transmitter output terminals, and an impedance created by 'action at a distance' through a transmission line. But if both kinds of load create the SAME steady-state voltage:current ratio and phase angle at the transmitter output terminals, then by definition they both have the SAME impedance, and the transmitter will respond in EXACTLY the same way. There is no steady-state measurement you can possibly make on the transmitter than can tell the difference between those two different kinds of load.

That principle is absolutely fundamental. It underlies all steady-state impedance measurements using bridges, network analysers etc. Regardless of the nature of the DUT (device under test), you connect it to the meter, measure what you find, and that IS "the impedance of the DUT".

The differences only appear if you change frequency, or if you make a time-dependent measurement, but there is never a difference in the steady state.

>Why do you imply that a virtual impedance can *cause* the

I invite you to consider another possibility: that the people who have chosen to stick with the established textbook analyses are not ignoring anything, and they are in no kind of logical trouble because those analyses are both logical and consistent; and that the only person in logical trouble is actually yourself, because you are making distinctions between different varieties of impedance that do not exist.

But WE DO enjoy the luxury of having complete information on voltages,
currents and phase angles, at any instant and at every point along a
transmission line. That allows us to obtain complete solutions without
dragging in unnecessary concepts from other disciplines.

Gee, Cecil, I'm sorry you've so completely misunderstood what I've posted on the subject. I've tried to be very clear about it, but I've apparently failed with respect to communicating with you. I'm sorry that's the way it is. Of course I don't consider myself an expert, so perhaps I'm excused from your catch-phrase classification of others who've accurately described the situation here.

I do not intend to. But it would seem sensible. If someone has no intension of selling something any more, it is hard to see what he/she looses by others having it. Obviously if they sell something similar, then I can see it would hurt them. But if they simply have given up selling software like it, then I see no reason it should not be free.

I'm not sure if you can get 8 or 9 now. Perhaps 9, but I've not seen 8. Must admit I have not looked too hard. I am typing this on a machine with Solaris 10

Solaris 10 really is excellent value. Use it on any machine, with any number of CPUs, commercial / hobby / educational, and it costs you $0.00.

I've seriously considered deleting Vista from my laptop and putting Solaris on that. But I know it will be a pain to get it all working, drivers etc.

> There is an open source version of Solaris 10, however that only supports
> the UltraSparc II and later processors.

That is not true. OpenSolaris runs on x86 and x64 hardware. I know that,
as I installed it myself.

Or perhaps you mean it does not support early *SPARC* processors. If so,
I would agree with you.

> Solaris 7, which was available for shipping costs, was originaly released
> at about $500 and derivative versions (e.g. Tadpole's) were never free.

Yes, I bought 7 myself for shipping costs. Strange thing is I wanted to
buy two copies - one for me, one for someone else. Sun would not allow
me to order two though! Some silly reason - I forget what it was.

> Anything older is long gone, and not available from SUN.

I think there are plenty of sources in Sun which will give this sort of
stuff away.

Message-ID: <472f640c$0$17940$4fafbaef@reader1.news.tin.it>
Source record: 34516

Everyone knows that radiation is caused by RF current flowing through a conductor: the higher is the current, the higher is the radiation intensity. That statement (which is anyway true) could lead us to erroneously conclude that antennas showing a low impedance at the feedpoint behave better than high-impedance antennas. For instance an RF power of 100W into a 5-ohm antenna cause an RF current of about 4.5A, whilst the same 100W RF fed into a 100-ohm antenna only cause an RF current of 1A. This is obviously a trick, but a well thought-out explanation could be of interest for many.

GPL'ed software has to be released with source code, which means work for the developer. If he/she has lost interest, they are not likely to dig out the source and make it available.

I think there should be an automatic right to use the software after (say) 8 years of no updates, no sales and no similar product from the same developer. But I don't feel sufficiently strongly about it that I will lobby my MP about it!

Yes, you can. I did it recently for a Sun4m computer.
>
> That is not true. OpenSolaris runs on x86 and x64 hardware. I know that,
> as I installed it myself.

Totally irrelevant. There are NO old SUN machines with X86 or X64 processors.
SunOS 5 has been available for X86 computers since Sun bought what became
it from Kodak. However it's only been about years that Sun has sold X86/X64
computers.

>
> Or perhaps you mean it does not support early *SPARC* processors. If so,

That's it, you said old Sun computers.

> I think there are plenty of sources in Sun which will give this sort of

Sure and there are plenty of people who have it and will send you a copy,
plus a few "archive" sites with SunOS 2 and 3, but they are either
outside the U.S. or will publicly deny that they exist.

Geoff.

Ian White GM3SEK wrote:
> Any device that creates those same electrical conditions possesses the
> same impedance; by definition.

Sorry Ian, that's just not true. There are three separate
definitions for impedance in "The IEEE Dictionary". If all
those were the same impedance, they wouldn't need three
definitions. A resistor has a resistance. The Z0 of a
transmission line is a resistance. They are NOT the same
impedance, by definition. The IEEE Dictionary says:
"Definition (C) is a second use of "impedance" and is
independent of definitions (A) and (B)." (C) is the
definition of impedance associated with a resistor,
inductor, or capacitor. (B) is the definition of impedance
associated with a voltage to current ratio. The IEEE
Dictionary goes out of its way to explain that there is
a difference.

Although they may have the same value of impedance components,
they are NOT the same impedance, by IEEE definition. See above.

> That principle is absolutely fundamental.

Too bad that your underlying absolutely fundamental
principle is wrong according to the IEEE Dictionary.

> ... because you are making
> distinctions between different varieties of impedance that do not exist.

I'm just following the IEEE lead. You, OTOH, are in
logical trouble for disagreeing with the IEEE.

Could you be a little clearer? Does a reflected EM
wave have an associated ExH power density? Does a
reflected wave obey the principles of conservation
of energy and momentum? Is there exactly the amount
of energy in a transmission line needed to support
the measured forward power and reflected power?

Copyright is (virtually)forever, regardless of any aspect of whether the work was or is for sale or not.

One cannot, for instance, make a legal copy of an original (film) print of Disney's "Snow White", if you happened to have such a thing, even though Disney doesn't sell it (and never has, actually. prints are just rented or loaned)

> I don't see any reason to not acceed to his request.

Well, since its still covered by copyright, it wouldn't be either legal or ethical to do so.

> Ofcourse so few people pay for computor programs these days but I like
> to do things right,
> after all if a patent is abandoned then it is a free for all since
> the advance of science cannot be stopped and it becomes freeware

Patents have a relatively short term (20 years now), and have a whole aspect of "all infringers must be pursued", which does not apply in the case of copyright. You do NOT have to purse all infringers of copyright to keep the protection in force, and the term of copyright has been extended over the years.. 50 years after the author's death, I think (and Brian is still alive...)

Lest you be thinking of one of the "fair use" exceptions, you'd have a very tough time justifying it for software. Same for the "library making copies of out-of-print or hard-to-find books" exception.

Stanford University has an excellent site with summaries and gory details on copyrights, particularly with respect to "fair use".

Actually, odds are that you do not OWN the software. You probably licensed it, and you'd have to look at the license terms to see if it can be "loaned". Most licenses prohibit loaning.

> Shame that it is being squirreled away so nobody can use it
> especially since it is still considered the best there is.

Considered by who? It's certainly convenient and structured in a way that fits well with ham users, but for antenna optimization in general, there are an awful lot of very sophisticated programs out there.

I believe that the reason he doesn't respond is that he (justifiably) felt taken advantage of by people who duplicated his software without paying for it. So, he decided "well, if that user community can't be trusted.. I'm not interested in providing support."

My interpretation, not Brian's.

Nope..
The license agreement apparently reads along the lines of:

This software is copyrighted. It has been provided to
you on the condition that you will not sell, rent, lend, give
away, or otherwise transfer the software to others.

> Seems wierd to me that a patent costs a lot of money to get

Different legislative history, different industries, etc.

Copyright didn't used to be that long a term. And, copyright has
interesting things like fair-use and compulsory licenses (thank you
player piano manufacturers).

Assuming the author actually wants this to happen. Heck, the author could go one step further and just declare it to be Public Domain.

However, there are good reasons why an author may not want their software used. Maybe it has an egregious bug that would lead to endangering public safety? Maybe it caused some legal problem and the author has been required to cease distribution and support? Maybe the author just decided to not have anyone use it anymore.. It is the author's *right* to do so, which is why it is called copyright.

Also, don't confuse copyright (which controls copying) and any licensing agreements (which might control copying, or use, or anything else).

I've done software for which copyright protection was immaterial, since it was protected as a "trade secret" and it was licensed under the condition that the user not further disclose it, with substantial liquidated damages if they did.

Under the GPL the software can then be modified , sold by

Denny,
First of all I never said I was giving a lecture but I can see how this
could be a logical assumption. I dont need to be an expert or want to be
one. I just said I wanted to collect some data. If I were comparing a quad
to a yagi my task would be no problem. I just cant find any info on a 4 or 5

element quagis. My assumption is that a quad would be the higher gain antenna when this number of elements are involved. I can understand why this information would be hard to find but thought that if there is any place it can be had it is here at RRAA. I have found one reference that implies that a quagi by definition is 6 elements or more.

Like most hams I have no way of making the measurements you suggest. It must be nice to live in a world where you would assume I could.

All I really need is data I asked for. If someone aske me a question I dont know I have a good answer for them, "I dont know". I dont "wing it".

Sincerely
Jimmie

The problem isnt what you put under the magnet, most magmounts already have some sort of protective film. The real problem is getting dirt under them. Just one grain of sand will ruin a paint job. Having a big spot that doesnt fade with the rest of the car will ruin a paint job. Drill the hole.

WHY always an ODD number of elements?

I can understand three: reflector, driven, and director, but I don't
understand NOT four: reflector, driven, 1stDirector, 2ndDirector ???

Ian, an excellent and quite comprehensive treatment.

Sal,

Some folk will try to distract from an adequately accurate approximation (being the steady state solution) by wanting to descend to a time domain solution which as you note converges to the steady state solution in time, but is much more complex to solve.

The relevance of steady state solutions is demonstrated by the traditional methods of designing transmission line transformers (eg quarter wave match), stub matching schemes, the application of the Smith chart etc. These things are only valid on applications where a steady state solution is valid, and the widespread use of them attests to the widespread existence of systems that are quite adequately analysed by steady state methods.

Most ham applications are ones where the highest modulating frequency is very small wrt the carrier frequency, and are emminently suited to steady state analysis.

Similarly, consider that when steady state analysis is not appropriate, then many of the devices mentioned above may be inappropriate as they will cause distortion of the signal.

It seems to have been extended to prevent the Mickey Mouse copyright from expiring. See, for example, http://writ.news.findlaw.com/commentary/20020305_sprigman.html. The extension was challenged in court, but the Supreme court ruled in Mickey's favor.

I have an explanation.

This is a classical example of applying a simple rule (field is proportional to current) without understanding its meaning or context.

The first thing you should always think about is the law of conservation of energy. If you put 100 watts into an antenna which draws 1 amp and it radiates, say, 99 watts (the remainder going into heat), then how much power should you expect to be radiated from an antenna drawing 5 amps and consuming 100 watts? If your answer is anything over 100 watts, then there's not much point in continuing the discussion until you gain a grasp of the most fundamental of physical principals, and in the meantime you're the natural prey of all sorts of scams including perpetual motion machines. If your answer is 100 watts, then your theory dictates that antennas with less than 5 amps feedpoint current must radiate less. All the power going in must be either radiated or end up as heat, so if the lower current antenna is radiating less, there must be more heat. What does the theory say is the cause of more heat being generated? After all, it's proportional to the square of the current, not just the current, so a higher current antenna should radiate a smaller fraction of the applied power, not more, than a lower current antenna (which, in fact, it generally does).

The next thing to realize is that the strength of the overall radiated field from the antenna is *not* necessarily proportional to the current. It is for a single antenna, but not when comparing one antenna to another. What's proportional to the current is the *field*. In some types of antennas, intense fields can be created by high current, only to partially cancel each other. The field is intense close to the antenna, but not very far away.

And then you need to consider that the radiation is proportional not only to the magnitude of the current, but also the length of conductor on which it's flowing. So a short antenna with high current radiates as much as a long antenna with low current. Knowing that, think about how

you'd get an antenna to present a lower radiation resistance so the current would be higher. One way is to shorten the antenna. Hmm. Interesting how that works out, isn't it? There's also the matter of current distribution. On a long antenna, the feedpoint resistance might be fairly low, indicating heavy current at the feedpoint. But a quarter wave or so down the line, the current can be very low.

Another way to lower the feedpoint resistance is by mutual coupling. A W8JK array -- two close spaced elements fed out of phase -- is a classic example of an antenna with low feedpoint resistance. Both elements have high current and create intense fields. But the fields from the elements at least partially cancel in all directions. So the power in the overall radiated field is, except for loss, the same as for any antenna having the same input power. As it must be.

The same kind of field cancellation can take place in single antennas, with the fields from one part of the conductor interfering with the fields from another. Again, though, the total power radiated must be the applied power minus loss.

In fact, low radiation resistance is often an indicator of an antenna that's high Q -- that is, it's radiating relatively little compared to the intense local fields it's generating. This makes a narrowband antenna, and one that's potentially lossy. If you need more current for a given power input -- and radiated output -- then you suffer from greater I^2*R loss. So it's likely to be not only more narrowbanded but also less efficient than a comparable antenna with a higher radiation resistance.

Interesting, when I replaced the mica insulator on a screen bypass cap with
Teflon the capacitance increased. I guess this is because the Teflon was
considerably thinner than the mica.

That would be the reason. The dielectric constant of mica is around 5-7 depending on the type. So for the same thickness, mica would give you at least 2-1/2 times the capacitance of Teflon.

Dielectric constants for a wide range of materials are readily available on the web. Google is your friend.

I have found that the separation of the wires, as close to the feed point
as possible matters more than the seperation further away from the feed
point.
My wires were only 12 inches apart over there total length but were 12
inches apart, about 12 inches from the feed point.
I had very little interaction when I tuned it.

Hi Jimmie

Mt Cebik has some words on this.. I'll admit I didn't read it, only searched for the word on his site.

http://www.cebik.com/vhf/qy.html

Might be a good place to start.

I note your reluctance to model antennas. This is however a great technique you can deliver to your club members!

Cheers Bob VK2YQA

Hi Jimmie

EZNEC isnt restricted totheoritical antennas. I use it alot to get data
for my real antennas. I can get better information on my antenna designs
with EZNEC than I get with the actual pattern measurement.
I am an old guy with almost no computer skill. But, EZNEC has been very
easy for me to use. I got a good head start from a couple aarr regulars,
so I didnt even need to read the instructions.

> Roy Lewallen, W7EL

Everything that Roy has stated above is based on radiation theory and
not actual facts.
The theory consists of a theorised chain of thought based on
observables without knowing exactly
what is happenning which is why scientific thought still searches for
real understanding of radiation.
True, the essay by Roy may well reflect what is said in some books and
if science is rules by polls
then we can say that what is in the books is fact.
You might well ask what is the hang up?We know that a time varing
current creates radiation
which is exactly what the problem is. Does a time varying field creat
radiation as in
current of a sino soidal form or does this time variation set up a
position that LEADS
to radiation? You will see that the books dwell on resistance, current

and voltage yet
a radiator must have distributed capacitance and inductance as well as distributed resistance.
On top of that "we all know" that these three items retain energy as well as releasing energy
but when energy release happenes it is not in sinosoidal form! If that is the case then
one has to take into consideration the time constants of these three items which present theory
in the books do not address . Nor is the rate of collapse of various fields that accompany
a varying current addressed which must wait for the time that the true nature of radiation is known.
The true nature can only become known when inductance and capacitance collection
and release of energy and the associated change it has on time with respect to current flow.
Review of Gaussian laws point to radiation as being the result of occillation created
by a tank circuit which in mechanical form is seen as a pendulum which conforms to Maxwells laws
but for unknown reasons scientistists have not got around to backtracking over past history
to determine how such a mystery can have lasted so long especially now that we have computors
to gurgitate unknown amounts of "prime" information.
It is,ofcourse to early to accuse Roy of putting out false information, only time can tell.
But what we can say that radiation theory is just that, a theory thought up to concurr with
observables

> has been replaced by an impedor with a resistor, inductor,
> and/or capacitor.

The final of the HT is optimized for transmitting into a 50 ohm impedance. The type of impedance does not matter at the frequency in question except that complex conjugates must be used.

Taking the derivative of Pload with respect to Zload and solving the max/min equation for zero slope, the resulting equation is Rload = Rsource and Zload = -Xxcvr. This is when max power transfer to the load occurs. So when Zload (=Rload + Xload) is GT or LT 50 ohms, much of the power in the circuit is dissipated in the Rs portion of source impedance as heat. The "coolest" operation at the transceiver final will always be when Zload = Z transceiver whether Zload is an antenna or a resistor.

However, note that I am using absolute values here due to my asciii challenges. For a purely resistive load, than Rload = Rosurce for max power trnasfer. For a complex load, Zload equals the complex conjugate of Zxcvr for maximum power transfer (capacitive to inductive etc.).

This is America! The two words you used don't have meaning anymore.
As Roy would say the reaction is "justifiable"
Legal is a reference to law, federal law, but that only comes into
place at the whim
of some public servant. On top of that it is to slow to be a
deterrant.
Ethics is something based upon religeon but in America every thing is
based on results
for which the reward is money. There are many a religeous person who
will turn to the gun to deter abortion as well as chemists who will
not sell birth control pills
to the public. Both of these are against the law but the accused say
it is ethics which "justify"
can be used. Again this is a capatalistic country and shooting in the
back
is allowable in the absence of laws. You voted like other Americans
for a
government that provokes wars, lies and tortures, so would you
describe efforts to dethrone Bush
as being something unethical which is also against the law? The demand
for ethics

is now only used in America by losers when law is not on their sidea
and laws are purchased
using money .
As Cronkite would say " that's the way it is"

But I would run a lot of theoretical antennas if I had it. I can see me
wasting a lot of time with it.
Granted it would be great for he project I am trying to do now and I am sure
its a great product.

Jimmie

Hi Jimmie

Forgive me if I sound flippant. But, this "computer modeling tool" isnt
intended to be a time wasting device. There is no reason to think of it
as just a "theoretical" program. EZNEC shows you quickly what your
antennas can be expected to do in Real Life. I consider EZNEC to be one of
the finest electronic/antenna tools a person can buy. And, if finances
are tight at this time, Roy is willing to let you use the program without
any money trading hands. The program would be an excellent way for you to
gain the confidence you are looking for when discussing Antennas with your
associates.
My advice to continues to be "try it, you'll like it".

Yeah -- well, I was trying to keep it simple, as I said to start the second paragraph.

Tell me something, please: with a mismatched load, isn't overheating of the transmitter sometimes a risk? (Assume no tuner, 50 feet of coax and an assortment of attempted HF transmit freqs.)

> How much of the reflected energy is dissipated in the

... and I think I see an example of the "astute choice" illustrated by the "ladder-line length selector for our all-band dipole" on your website. I get that and I like it but it would never have occurred to me -- probably because of lack of wave theory on my part. Am I right?

Thanks.

There a re a few that already do it i wil probably go to them to model some short boom quagis, after all it is a club project.

>
> Cheers Bob VK2YQA

Thanks Bob Bob, there is plenty of information on quagis 6 elements and longer. I was hoping to find some info on a 4 or 5 element quagi. In that area I am expecting the gain of the quad to be greater than the quagi. I realy dont mind modeling antennas, I just havent felt the need yet.

I got roped into this project because I interjected into the conversation on quagis that I saw one in 1970, that raised a few eyebrows. A CBer had his Moonraker 6 damaged by lightning and had to replace the driven element. Since the reflector was already in a quad configuration, he was familar with quad antennas, so he replaced the driven yagi element with a quad element. Perhaps what I saw was the first quagi but I doubt it. Farm boy engineering at its finest, no doubt about that at all.

> Zxcvr for maximum power transfer (capacitive to inductive etc.).
Correction to typo:

Taking the derivative of Pload with respect to Zload and solving the 1st
year calculus max/min equation for zero slope, the equations resulting in
zero slope (max power) is:

Rload = Rsource

Xload = - Xsource.

This is when max power transfer to the load occurs (where Zload = Rload +
Xload and Zsource= Rsource + Xsource).

Note that when impedances are mismatched and also complex, not all of the reflected power is real. There could in theory be a completely reactive mismatch with zero power dissipation (heat) at the transmitter. However, radiation resistance is not reactive and is in phase with the source resistance, thus this component of the total impedance could cause some, or a lot, of heating if not properly matched. This basically supports what Cecil and a few others are saying.

I have spent about 4 months on 2m antenna test range playing with Yagi - Quad - Razor (Quagi) designs. (before modeling software was available) Design objectives were to obtain best gain, F/B - clean pattern aand 50 ohm impedance.

My findings were:

The maximum performance for 3 el. antenna was obtained from 3 el Quad. The rule seems to be quad elements work best with one on the front and one behind the driven quad element or log cell.

For 4 el. parasitic antenna it was 3 Q and 1 Y element.

For 5 and 6 el it was 3 Q 2 (3) Y

For 7 el the winning combination was Y refl. Q refl. 2Q log driven cell, Q dir. 2x Y dir.

For over 7 el. I would just keep adding Yagi directors.

See http://www.k3bu.us/razor_beams.htm for some pictures on the cover CQ Magazine featuring stacked 15 m 7 el Razors.

Hope it helps.

I think this is close to what I have been saying with the simple calculus max/min impedance match equation. When the reactive portion of the energy is sent back to the load several times it 'eventually' gets transmitted out and not all (or even most) of the energy is dissipated into the PA finals. Also, some is dissipated into the coax and this can be minimized by using a good ladder line even when SWR (mismatch) is high. In some cases, the source may heat up severely when mismatches between radiation resistance and source resistance are extreme, for example the antenna output is shorted (zero ohms) or open (infinite ohms).

Source record: 34403

Think, this is the same thing that one "Kurt N.Sturba" says in
his columns, about swr: It Isn't LOST power
(Heating the final or , dissipated in the final),
but is redirected to the load (again). Tho might be sticking
my foot in mouth again, but the ONLY effect of SWR, would
be on the Transmission Line (because of the loss of THAT line)
First, because of the loss, to the load.
Second , because of the Reflected LOSS (again!)towards the Source.
And then The loss, as it is again redirected towards the
load! In short, SWR, doesn't effect the power-- the FEEDLINE does
and the higher the swr- the higher the loss the feedline presents to
the load! See World Radio magazine for his tomes! In short ,
MAXIMUM power transfer occurs when the impedence of the source= the
impedence of the load. But that doesn't mean that the power is lost
at the SOURCE as (heat, loss, ect). ANY loss must be in the (devices)
between the source , and the load! Jim NN7K

No but I can turn it in to one is the point I am trying to make. Something I
dont need to do while I have so many projects going on. Many of them have
gotten far behind because of recent surgery. Antennas and ham radio are just
a couple of the things I am interested in. Lately I am trying to keep myself
limited to things I can share with my family.

I'm backing Roy with this one. That said, my old college lecturer used to say that an antenna was simply a device to match the impedence of the transmitter to the impedence of free space (around 377 ohms). With variable output impedence valve transmitters, this idea was a lot easier to grasp for many students.

Now that modern solid state transmitters are pretty much standardised at a 50 ohm output impedence, the antenna often needs a little help from an antenna tuning unit or a specific design to match the 50 ohms to 377 ohms.

For example, resonant dipole antennas typically have an impedence of between 30 and 75 ohms (depending on mounting height and surroundings). That is the impedence that is presented to the transmitter. However at the point of the antenna where the signal is actually radiated, the characteristic impedence matches that of free space, 377 ohms. Yes, that's right. Not all the length

of the antenna is radiating, just the bits where the impedence is closest to 377 ohms. All the rest of the wire is just there to make the appropriate transformation ratio.

I can hear the cries of disbelief now! I should point out that this is neither a new or an original idea, just in case anyone is thinking of patenting it.

If an antenna is designed so that it doesn't have any point that matches the impedence of free space, then a mismatch of impedences occurs and the antenna radiates less efficiently. The antenna may still show a 1:1 SWR reading at the transmitter with no indication of any problems. The 'wasted' energy generally ends up being dissipated as heat or coronal discharge. Bearing in mind just how sensitive most receivers are, an antenna which is only 50% efficient will still put out a signal that is less than an S point down on one that is 95% efficient and you are still highly likely to make plenty of contacts. For low frequency working, antenna efficiencies of only fractions of a percent have been shown to be effective in making trans Atlantic contacts.

Of course it does take a kilowatt to produce a single watt of radiated power, but that just goes to prove that you can get a signal out in two ways; match impedences for efficiency or chuck a load of power into the proverbial bit of wet string. That's why long wave broadcast stations use transmitter powers of up to 5 megawatts!

Well that should throw the cat among the pigeons...

No, I'm sorry, Cecil. I've tried, but I'm afraid I'm just inept at communicating. I take all the blame for it. However, life's too short to spend a lot of time worrying about it, and I need to get back to calculating the even and odd mode impedances of some coupled line structures now. I just hope I don't have too much trouble applying the results to some real-world problems.

Roy,

I don't cling to anything, desperately or otherwise. I keep an open
mind. I've learned a lot but I haven't learned everything.

Give me credit for having been the victim of conventional wisdom or
[insert your favorite disparaging term for misinformation]. It's that
simple.

Oh, and keep that "black cat" metaphor handy for any ol' time you want
to piss somebody off. It works.

Hmm...And at the points that match the 377 ohm what exactly is passed
over (transferred) and how?
Since the term impedance comes from the word to impede it would
suggest that the higher number
impedes the transfer of whatever at the highest impedance point! Did
the lecturer
hint in any way what was being passed to that which had this 377 ohm
impedance.
As for longwave broadcast stations using large amounts of power it is
well known
that if you can't speak the language then an increase in sound levels
is a natural response.

I'm sorry you trimmed out and ignored all the yes/no questions that I posted. One wonders why you guys refuse to answer simple yes/no questions. Here one again:

Does a reflected wave possess energy proportional to ExH, i.e. the cross product of the E-field and the H-field?

Given the magical thinking on this newsgroup, it is pretty obvious why you guys cannot afford to answer that question.

I think we were / are all vulnerable to learning from each other... it is what amateur radio is about, the collective 'self training' that is part of the ITU defintion of the amateur service.

Like yourself, I learned from the hobby elders, and some of it, a lot of it was BS, and I freely admit that I am uncertain of some of what I 'know'.

We all need to test our own 'knowledge', especially the widely held stuff that you just don't find in reputable text books. You have to ask have we hams got an edge on the rest of the world, or is the proposition a myth.

A few years ago I worked on development of a handbook for our new six hour hams. It was a considerable struggle to keep the 'reflected power is dissipated in the PA and causes damage' myth out of the handbook that would feed the hobby intake in this country.

Imagine a multiple choice question in the assessment:

Reflected power:
a) increases the power bill;
b) is a technique for operating 12V equipment in modern 24V vehicles;
c) reinforces your signal provided it is re-reflected by an ATU;
d) overheats transmitters causing serious damage;
e) is a fire hazard.

You haven't commented yet pro or con, but if I may, I want to expand on the observation I made about your variable length twin-lead arrangement being an "astute choice" to promote complete constructive interference in the direction of the load.

If the line length will bring this about as you have demonstrated, does this mean that a tuner appears to adjust the effective line length (from the perspective of the source)? The only explanation of a tuner I have seen describes it as creating a stub whose impedance, in parallel with the impedance of the transmission line/antenna system, is seen as 50 ohms, a presumptive good match. I don't know enough to accept or reject this notion, so I shall do neither at the moment. However, I think of a stub as shunting a transmission line, whereas the tuner is electrically in series, so maybe something's fishy about that. I withhold judgment.

More to the point, when I was taught transmission lines, they were diagrammed with lumped constants: series resistance and inductance + shunt capacitance. The internals of a pi tuner are just more of the same and would seem (by intuition, alone -- I am not claiming anything) to behave as an adjustable length line, minus the resistive component. By extension, Does a T tuner cancel some of the reactance of the line in which it is inserted, thereby effectively shortening the line. (The phase "conjugate impedance" is poking out from a fold of my brain.)

Am I onto something or have I simply launched myself into the eye of another shitstorm?

"Sal"

Thanks for the support, but I disagree with your college lecturer. The impedance of free space has dimensions of ohms and the output impedance of a transmitter (not necessarily 50 ohms, but designed to work into a 50 ohm load) has dimensions of ohms. But they're not the same thing. The transmitter impedance is a ratio of voltage to current while the impedance of free space is the ratio of an electric to magnetic field in a plane wave, or the square root of the ratio of its permeability to permittivity. If all an antenna does is match the transmitter impedance to that of free space, why can't you just hook a transformer to the rig's output and let the secondary leads dangle? Or, why can't you put your signal into a 300 ohm twinlead transmission line and spread the conductors until the Z0 is 377 ohms in order to "match" the impedance of free space? I look at an antenna rather as a transducer, which converts energy in the form of voltages and currents in conductors to energy in the form of electromagnetic fields in space, much as a speaker converts voltages and currents into mechanical waves in air.

Let me be the first to cry in disbelief. Being that it's not a new or original idea, perhaps you can direct me to a text where this is explained in more detail. I don't believe I've ever come across it in the 8 or so antenna texts I have on my shelf or hundred or so papers in my file. How do we identify these unique points on an antenna? Does an antenna with two such points radiate better than an antenna with only one? Where can I find information on optimizing an antenna to maximize the number of 377 ohm match points? I do professional antenna design on a consulting basis, and I really need to know if the theory I've been using for all these years to design antennas is faulty, and how I can take advantage of this knowledge!

Of course an antenna can read 1:1 and be highly inefficient -- a dummy load is such an antenna. And it can read 10:1 and be 99+% efficient. SWR isn't an indication of efficiency.

But the only mechanism I know by which heat can be generated by an antenna is by current flowing through a resistive conductor, in which case it's I^2 * R. So either your example antenna has some way of increasing I, increasing R, or creating heat by some other mechanism. Which is it? How can I calculate it?

Art,
now you are just nitpicking...
the observable facts (those that relate to radiation 'theory' to 5 9's
accuracy) should be more than enough. there are just some things that
science yet knows about the universe.

those field could be transferring energy in some 'quantum' function that has
yet to be devined.

However, what roy says can be observed to such an extent that it pretty much
becomes observed facts and not just theory.

and yeah, my quip about ohms law may be a bit over simplified (and wikipedia
is a wonderful resource for little tidbits of information).

Hi John,

My path up through "A" school was through the Radar branch (I was the
only ETR2 in the Communications Branch when I taught there). The
Radar training gave us hands on experience with equipment that
presented both lumped (pulse forming network) AND line (Magic T and
such) designs. Also, reflected POWER was palpably lethal in both
applications. Melodramatic criticism of the fine points in
terminology carried little weight in lab exercises.

Luckily, I had the presence of mind as a student to hie myself into
Frisco to buy Terman's "Electronic and Radio Engineering." The Navy
course of instruction and training manuals so perfectly dove-tailed to
that book that the fit was a precision match. The "A" school syllabus
didn't go nearly to the depth of detail as offered by Terman (the
ET1&2 and ETC course work did), but it did heavily touch every chapter
found in that tome.

Insofar as heresy, the syllabus was rife with it. We taught that
antennas that were too short could be made to appear longer by the
addition of the "missing" wire in the form of a coil. Similarly, a
too long antenna could be reduced in length by inserting a capacitor.
The teaching aid was to think of the coil symbol as a spring that
could be stretched to lengthen the short antenna, and cap symbol as
providing space enough between the plates to collapse the extra length
of a too long antenna. Clearly the metaphors wheeze, but are
effective well beyond mathematical proofs that could only serve as
sleeping pills.

Before the purists roll their eye's and mutter "tut-tut" under their
beards - instruction was complete to point out these were short-cuts
as memory aides and did not serve as a complete discussion on the
topic. Reflected power certainly fell into that category as its
hazard was positively destructive and not a mental exercise subjected
to debate in a perfumed symposium.

Anyone with radar experience can fashion the plumbing to steer
reflected power to any load. -um- reflected energy be damned at that
point as any reflection was inherently returning to a source that was

long dormant (in terms of microseconds) and ready to dissipate anything that came down the pipe. The whole point of the magnetron's success in war was its robustness in the face of catastrophic mismatches. The PFN might flame out or the thyratron burst, but the magnetron would survive.

Hi Antonio,

Feed point impedance is basically not related to radiated power.

A halve wave dipole in free space has about 50 to 70 Ohms impedance
(depending in thickness of radiator and when in resonance). However
the same dipole close to a large metal surface can have 5 Ohms of
input impedance.

There is more current in the radiator, but also a nearly opposite
current in the ground plane that cancels the radiation in certain
directions.

Another example is the thin end-fed half wave monopole. That has an
input impedance (real value) in the 400 to 5 kOhm range (depending in
thickness of radiator). So the input current is low, but the current
near the middle of the radiator is high.

When you put an end-fed HW radiator close to a ground plane, the end-
fed input impedance increases further (assuming losses are
negligible).

In general, the amount of radiated power is not determined by the
input current, but by the total distributed current in all parts of
the antenna that carries the RF current. Manual calculation of
radiated power (based on the produced 3 dimensional field) is possible
for very simple antenna constructions only.

Best regards,

Wim

> Am I onto something or have I simply launched myself into the eye of
> another shitstorm?

A single series length of transmission line can only transform impedances to other values located on the SWR circle (or spiral) on a Smith Chart. There is only one low resistance value on that SWR circle and it is equal to Z0/SWR. For instance, if the SWR is 9:1 on 450 ohm line, that value is 450/9 = 50 ohms. If the SWR is 4.5:1, that low resistive value is 450/4.5 = 100 ohms. If the SWR is 18:1, that low resistive value is 450/18 = 25 ohms. Only one value of SWR (9:1) on Z0=450 ohm line will transform the impedance to 50 ohms. Since my transceiver is happy with any resistive impedance between 25 ohms and 100 ohms, I am satisfied with that maximum 50 ohm SWR of 2:1.

An antenna tuner not only can perform the equivalent of the above transformation but it can also do the equivalent of a transformation of the resistance value to 50 ohms for any SWR within the range of the tuner. So a tuner can transform 25 ohms or 100 ohms to 50 ohms. A tuner has one more dimension of matching than does a single series transmission line.

Adding a tapped transformer to a variable length transmission line system gives it that extra dimension. A second/third section of transmission line in the form of a stub will also add that extra dimension.

The main function of matching is to stop reflected energy from reaching the transmitter leaving it no other available path except back toward the antenna. That is done by tuning for a Z0-match at the transmitter. A tuner is only one way of achieving that Z0-match to 50 ohms.

Hi Roy

Back when I was first studying electronics and transmission systems, all high power HF commercial transmitters were still using valves. By careful design of the output stages and loading systems it was indeed possible to spread a couple of wires out from the back of the transmitter and achieve a usable match. Working in a marine environment the antenna impedences varied constantly and the commercial transmitters (which were all of an identical design) needed to be able to cope with virtually any antenna system they were connected to. Exactly the same design of transmitter could be fitted to a fishing boat or a supertanker, with all the attendant differences in antenna lengths and heights.

From my lecture notes, we were told that there are essentially only two types of antenna, the monopole and the dipole. The monopole is usually mounted vertically and relies on the earth (or water) to provide an 'image' to work against. The dipole can work in the absence of an earth as each half works against the other. This was explained by quoting Newton's Law that every action has an equal and opposite reaction. So each half of the antenna system must balance in order to radiate a signal. Loop antennas are simply dipoles where the ends are folded around. Yagis and other arrays are simply ways of putting more wire in the air and obtaining a measure of directivity by virtue of re-radiation from the elements causing constructive/destructive interaction and focussing the gain in a particular direction. Similarly the radiation points in multi wavelength antennas interact to provide directivity. It's all very simple, apart from the math. The interaction of a transmitted signal with an image reflected from the ground is also the reason why signal take off angles vary with antenna height.

Taking a resonant half wave dipole cut for say the 20 metre band. The characteristic impedence if mounted a few metres above the ground will be around 50 ohms at the feed point. This provides a good match to most modern solid state transmitters. At the feedpoint, the current will be high and voltage low. At the far ends of the dipole, there is no connection, so the current will be zero, but the voltages will be high. The current and voltage

relationship varies smoothly (actually in a characteristic distribution curve) along the length of the antenna and the characteristic impedence of the antenna varies from 50 ohms at the feedpoint to nearly infinity at the ends. It isn't actually infinity because the ends cannot be perfectly insulated. So at some point along the length of the antenna (about two thirds towards the ends) the impedence matches the impedence of free space, 377 ohms, and this is the point at which maximum coupling of the antenna to free space occurs and by inference where maximum energy transfer and radiation takes place. It can be mathematically demonstrated (and it's pretty obvious) that some radiation will occur anywhere along the length of the antenna, but that the maximum radiation and coupling occurs at the 'sweet spot' where the antenna impedence matches the impedence of free space.

For multi element and multi wavelength antennae, signals can be thought of as being absorbed and reradiated causing constructive or destructive interaction with the signal radiated from the dipole element and thus providing directivity.

I appreciate that this method of looking at antenna design may be somewhat archaic, (well I did work for Marconi), but it does provide a lot of the answers as to how and why antennas work in practice. I have never found this method to give results that sustantially differ from more modern methods of antenna design and it provides a simpler way of visualising what is going on in all those bits of wire and tubing.

I will have to have a trawl through my archives in boxes in the attic to see if I can find a specific text that covers these points. The books will probably have been originally published in the 1940's or 50's and refer back to research done in the 1930's. There was a lot of secrecy during these times due to WW2 and the subsequent cold war, so that may have been why these ideas were not promulgated more widely.

As for the heating aspect, because the impedence (resistance if you like) of the antenna is constantly varying along its length, the application of ohms law will work for specific points along the length of the antenna. Calculus and differential equations are needed to produce distribution curves for the whole length of the antenna.

For me anyway, visualising antennas operating in this fashion explains why electrically short antennas will never be as efficient as a full sized dipole (with or without extra twiddly bits bolted on the front and back). It covers why SWR is not the be all and end all of efficient power transfer and explains how and why directivity arises from multiple elements or wavelengths.

I can't claim that any of this is correct, and it may all be a huge commercial secret somewhere, but it works for me. But hey, this is rec.radio.amateur.antenna and not a PhD course in antenna design.

Cheers

Mike G0ULI

Hi Mike, please don't confuse characteristic impedance
with feedpoint impedance - they are not the same thing.
A dipole is a standing wave antenna and the SWR on the
antenna transforms the impedance from the feedpoint to
the ends similar to the way a 1/4 wavelength stub
transforms impedances. The characteristic
impedance (Z0) of a horizontal dipole wire above earth
is around 600 ohms and is relatively constant all along
the horizontal wire. The formula for the characteristic
impedance of a horizontal wire above ground is:

Z0 = 138 log(4D/d)

where 'D' is the distance above ground and 'd' is the
diameter of the wire. #14 wire at 30 feet is very close
to Z0 = 600 ohms.

Thank you Cecil. You are quite right.

I allowed the terminology to get a bit loose in an effort to try and keep things as simple as possible. I don't think it matters too much when just trying to visualise how the voltages, currents and impedences are constantly changing as you move from the feedpoint out along the length of an antenna and why antennas behave as they do.

It's obviously a very simplistic picture which becomes a lot more complex when dealing with non resonant antennas and all the other interactions that can take place. I don't think any of this is a threat to EZNEC et al. :-)

Actually, I kind of assumed they used something along the lines I suggested to calculate antenna performance. I've never really thought about it before... Perhaps I had better download a copy.

The RADIO ENGINEERS' HANDBOOK by F. E. Terman states in the 1943 edition (pp 770-771) that the field of a complete antenna may be calculated by summing the radiation from discrete elements of it that are so small that the r-f current in each of them is considered to be constant across that element, while accounting for the phase and polarization of each element.

Terman shows an equation for the radiation pattern of such elements, and while radiation is related to the r-f currrent in each element, there is no term relating its radiation to the impedance of free space. This means that relative field will be maximized where r-f current in an element is maximized for that antenna configuration, not where the impedance of an element (or complete antenna) matches that of free space.

So for a linear, center-fed, 1/2-wave dipole, maximum radiation occurs from those elemental parts of the dipole where current is highest, eg, at the feedpoint -- not at ~2/3 of the distance to the ends of the dipole.

Other engineering texts of that era, and also modern ones read about the same on this topic.

> energy!

That's a valid assumption since nothing can violate the
conservation of energy principle. But ignoring the
conservation of energy principle under the assumption
that the energy will take care of itself leaves one
ignorant of where the energy goes. If one doesn't know
where the energy goes, that's one's choice, but one
shouldn't turn around and present one's self as an expert
on the subject of where the energy goes. As someone said:
'I personally don't have a compulsion to understand where
this power "goes"', as if understanding might be an
undesirable thing.

> But countless textbooks show that it isn't necessary to invoke
> that principle in order to make a valid analysis.

It's obvious that you have never perceived the need to
know where the energy goes - that the energy will
automatically take care of itself - and that's perfectly
OK. I, OTOH, have spent considerable time and effort studying
and tracking the energy through the system in order to understand
how the energy balance is achieved and where the energy goes.
So which of us would tend to know more about where the
energy goes?

I have discovered that there is always exactly the amount
of energy in any transmission line needed to support the
measured forward and reflected power. It seems illogical
to me to argue that the energy is somewhere else besides
in the forward and reflected waves.

Hi,

I know a very few handheld scanner antennas come with one already built in,
but does anyone know of a
source (assuming they exist) for a BNC to BNC that swivels between them ?

Would like to add a swivel feature to a scanner antenna that does not
swivel.

BTW: any opinions on whether this degrades any signals, etc. ?

Thanks,
Bob

Mike, What you have shown emphasises the fact that radiation IS just a
theory
where even in the last fifty years different theories have come4 to
the fore
and where scientists still hold that the nature of radiation is
UNKNOWN.
In this particular thread we are bandying with the term impedance
because
it includes the content of distributed capacity and inductance. But
when
you get down to it, nowhere is it shown what the time constants are
of
either of these two items and exactly what they do when current
"passes" thru them.
We all acknoweledge their presence but we do not acknowledge in any
way their functions
when compared with what is understood about lumped loads. If they
really act the same as
lumped loads i.e. energy tanks, then they must also have a time
constant which is
mentioned no where! Now if Terman doesn't include the time constant in
his equations
there are some that would conclude that it therefore does not exist
just so they
can reinforce their adherence to present day theory, just by ignoring
their presence!
I have no problem with people following the dictates of a book if they
acknoweledge
that the book also states that it a theory and where its ommission in
multiple books
does not give it credability to it as being a fact.
Best regards
Art

Hi Richard,

Yes it does seem that high current at the antenna feed point (or elesewhere)
is equated to maximum radiation. If that were actually the case, then a
short end loaded antenna should work just as efficiently as a full length

one. After all, the current at the feedpoint will be just the same in both antennas. In practice this just doesn't happen, perhaps as Art frequently suggests, the accepted engineering texts are wrong (or over simplified to make calculation easier). :-)

Hi Mike,

In practice (and confirmed in both theory and in the field 80 years
ago by Brown, Lewis and Epstein) it does happen. As this must come at
some great surprise (otherwise you would have never penned the comment
above) you would do well to reconsider:
>perhaps as Art frequently
>suggests, the accepted engineering texts are wrong (or over simplified to
>make calculation easier).
which, on the face of it, is absurd.

All of this, of course, can be reconciled by simply reading those
books you and Arthur have condemned for burning. It doesn't take all
that much effort because this elemental topic is usually handled in
the first 30 pages - complete with as much math as would suit anyone
who can master algebra, and with genuine references to previous work
that delved into the arcana of differential equations (if you choose
to, and are adept to go there).

It's a decent start, however you must remember that power doesn't reflect or propagate. You can't add power algebraically, so you won't be able to take phase into consideration (sort of crucial if you want to show cancellation). You have to use a vector quantity. Once you change to more sensible units, you can produce a sum at each reflection and show how the total changes as a function of time. Remember also that the front surface continues to be irradiated at each t sub n, so the amplitude of the signal penetrating the front surface will be different at each subsequent t sub n.

Actually Art, I believe that the radiation is a physical phenomenon which is capable of detection and measurement. The theory lies in describing what that phenomenon actually is. Since it is only possible to accurately describe the properties of photons and electrons in abstract mathematical terms, it is not surprising that a certain amount of confusion exists as to what they actually are.

Antenna theory has been expounded upon ad nauseam in countless books and papers. Certain books have been adopted as standards and the most plausible theories accepted and used as the foundation for further work. This does not necessarily mean that those original books and theories were correct in every respect.

For a couple of thousand years, the majority of the world's population were convinced the world was flat, even though the Greeks had proved that the earth was spherical. The idea of the world being spherical just didn't work in people's everyday experience. People were also convinced the sun and stars orbited the earth rather than the other way round and (quite successfully) invented ever more complex theories to explain the observed movements of heavenly bodies. So the fact that an idea is held by the majority does not necessarily mean that it is correct.

I readily accept that my suggestions may not be correct, but they seem to fit observed behaviour rather better than some of the other theories I have seen in print.

Best regards
Mike G0ULI

Hmm, a "majority of the world's population" which seems to ignore the
majority of the world's population in this regard. You are merely
reciting the superstitions of those in western Europe who were living
in metaphorical caves and burning books (notably in Greek and Latin)
for fuel. India, China, and Arabia had contrary views to what you
have labeled as "People were also convinced."

>I readily accept that my suggestions may not be correct, but they seem to

As you've already pegged the meter at zero on observed behavior of a
short antenna, this suggests you should re-evaluate your reading list.
The stuff you and Arthur reject is covered very early in competent
sources and never exceeds the volume of text that has been dedicated
in these threads. These rambling threads are bloated attempts to
replace functioning theory with neo-superstitions that don't really
explain anything as much as to foster a mystical view of the shining
city on the hill.

Yes Mike it is a real problem.
In a way I would like somebody to come along and show that by
adding a time varience to Gauss's law of statics which changes
it from static to dynamic in conformance with Maxwell laws is
incorrect. People ask for the mathematics and then avoid them
like a plague since it brings the radiation theorem into doubt.
But very few in ham radio are competant enough to go thru the
mathematics to prove it correct or otherwise and yet spout
the equations that they have read in a book.
This points out that their memory is good even tho their
understanding of same is negligable.
If somebody, probably outside of ham radio, would come along
and point out the error in the mathematics I could go back
to the books and spout off the same things that other people do.

There was a posting from a N3GCO or something like that a few
days ago pleading for people to present mathematics behind
what is considered new and then he disappeared perhaps knowing
there was a possibility that somebody would put mathematics
in front of his eyes.
Maybe it will take a Prof Jeffries of Surrey University to
pop in on this group to bring in some order as to what is
legitamate and what is not, but that is highly unlikely and
I have to live with what I have got
Best regards
Art

Richard

I had to study all the conventional texts and math to pass my exams. What you appear to be suggesting is that for a given RF current at the feedpoint of the antenna, the efficiency of radiation will be the same for a full sized or electrically short antenna. Taken to a logical conclusion, it seems that you are suggesting that two six inch wires end loaded with suitable short inductive coils will radiate just as efficiently a full sized 20 meter dipole so long as the antenna current is identical at the feedpoints of the two antennae. While the math may suggest that this is the case, practical experience, in my case at least, has proved somewhat different. The smaller antenna may absorb the same power and have an SWR of 1:1. It just doesn't manage to broadcast the same level of signal as a full sized antenna.

If the point of maximum radiation were at the feedpoint, it shouldn't make any difference. Looked at from my point of view, the maximum radiation points would lie somewhere within the inductive loading coils and because of the inductive loading, the point at which the antenna impedence matched that of free space would be physically compressed into a short physical length with inductance changing more rapidly per unit length than with a full sized antenna. I believe that this presents a plausible explanation to account for the measurably poorer performance of electrically short antennae. It may not be strictly correct, but it's a good deal easier to picture than working through all the phase and vector maths.

I would never advocate the burning or destruction of any book(s), particularly as electronic texts are so easily altered.

Elementary texts on antenna theory or any other subject are precisely that. They are designed to present enough information as fact to allow you make basic calculations and predictions. It is only when you delve deeply into a subject that you come to realise just how much of that 'fact' is theory and supposition. It isn't that the information is wrong, it's just that it is incomplete.

I fully accept that the conventional ways are probably more than adequate for most people and most purposes. I offer my suggestions as an alternative method of visualising the way in which antennas work. I am not claiming any new scientific principles, or invoking previously unknown phenomena, just presenting a scenario that seems to match practical, observed antenna behaviour somewhat better than some other theories that have been put forward.

As I previously mentioned, these ideas were originally presented many years ago by my college lecturer to help students who were struggling with visualising antenna theory. (We still had to present examination answers in conventional terms). I found it helpful and of practical use, perhaps others will also.

Okay Richard,

I admit that I used a very Euro-centric, biased and inaccurate example, but
you understood the meaning. Unlike others, I am not suggesting that
conventional antenna theories should be rejected, just that it can be
beneficial to take a look from another viewpoint occasionally. Just as I
should have considered the other (more) learned ancient cultures before
making my previous remark.

A "short" and a 1/2-wave, center-fed dipole both will radiate nearly 100% of the r-f power applied by a source Z-matched to the antenna feedpoint Z, less any I^2R losses in the antenna conductors themselves.

The directivity of the short dipole will be about 1.5X, compared to 1.64X for the 1/2-wave dipole. The difference in directivity is due to the difference in their radiation patterns. The longer antenna focuses more of its total radiation at right angles to its axis than the short antenna does, and less in some other directions.

The difference in peak directivity (gain) is only 0.39 dB, which would be difficult even to measure accurately. For equal applied power there would be no practical difference in the performance of these antennas on a communications link.

If I have an 136' ant feed with 80' or so of ladderline. If I wanted to work it against ground for 160m use:

1. would it be better off if I fed it with both ends jumped together on the ant side of my tuner?

2. Or, would it be better off if I put a relay in at the feedpoint to jump two sections that way, and also close off the wires on the ant side of the tuner?

This is the key, basically it is the area under the current distribution
curve along the radiator. Short antenna might have a high current at the
feedpoint, but only small portion of the area under the curve distribution -
less efficient and higher ohmic loses.
3/8 wave vertical beats 1/4 wave - larger area under the current curve.

Hi Wim,

that is exactly the point!

I would add that the statement "field is created by RF current", though basically true, may be a bit misleading. It seems to give RF current the merit of generating the field, when that merit instead is with the RF power supporting the RF current distribution.

Reading that statement, someone may be led to devise methods of obtaining high RF current with low RF power (e.g. by lowering impedance).

Perhaps saying that the antenna "field is created by the applied RF power" may be more instructive.

Kudo'S Yuri for standing up for what you believe in.
The fatal key to this argument is not recognising that the
inductor stores energy and later releases it. The "later"
bit demands knoweledge regarding the time constant of the inductor
and the time at which all the measurements were taken.
Tthe current enters as a sinosoidal curve
where its energy is retained. When the energy is released
it is in the form of a higher current that depreciates
according to the inductors time constant. It is also obvious
that because the inductor impedes the current flow
(Slow wave) then the entrance point will be the hottest point.
Enjoyed the story

There's no power shown propagating. The quantities
in watts are the irradiance values in joules/sec/unit-area
existing within a unit-area on the surface of the thin-film.

> You can't add power algebraically, so you won't
> be able to take phase into consideration (sort of crucial if you want to
> show cancellation).

Any physicist should be able to solve this problem using
the data given. The reason you cannot solve it is that you
have apparently never understood the irradiance equation.
It is true that one cannot add powers algebraically but
powers (irradiances) are added all the time in optical
physics using the irradiance equation. (Powers do not
superpose. There is special equation governing the
addition of powers.)

> You have to use a vector quantity.

That's where you are wrong. One doesn't need to use
vectors. The only thing needed is the phase angle
between the external reflection and the 1st internal
reflection. You can figure out that phase angle by
knowing that the thin film is 1/4 wavelength thick.
If you cannot, I'll just tell you that the phase angle
between the external reflection and the internal
reflections is 180 degrees.

You have all you need to know to answer the question:
What happens to the total reflected power (irradiance)
in the air back toward the source when the first internal
reflection arrives assuming the reflections are coherent
and collinear?

I hope you will not go silent on this thread just because
you don't like the emerging technical facts. If you pursue
the discussion to its logical end, either you or I will
learn something new. I am eager to discover any flaws in
my technical logic.

Well, besides that, I do not understand what BPL is supposed to solve.
It was my understanding this was a solution to the "last mile" problem.
Given the infrastructure in todays society, this leaves a very thin
customer base that would even need to consider BPL as a solution.

Hi Antonio,

As others also stated, an electrically small low loss tuned loop (for example 3m diameter for 80m band) can carry very high RF current (with moderate input power). But because of the cancellation effect by the current at the opposite side of the loop, the far field is not that high (even zero perpendicular to the loop).

However the near fields (for example in the loop itself) can easily exceed the limits for human exposure. In the middle of the loop all near field contributions do add in phase (in both time and spatial).

Many EM software first calculate the current (densities) in the antenna structure (for example a NEC wire model of a 3D structure). After that the far field is calculated by adding the individual contributions of all current (wire) elements for all 3D directions.

When the 3D radiation field is known, one can calculate the total radiated power by integrating the power flux density (Erms^2/377) over the full surface of an imaginary sphere. When the structure has no losses, the radiated power equals the input power.

As many antennas use standing wave resonators, the antenna input impedance is strongly dependent on were you feed the antenna (in a current or voltage node). The FD4 for example uses off-centre feed to avoid high input impedance when the antenna is a full wave (or multiple of FW) long.

An example of a completely non-radiating structure with very low input impedance (so high feed current) is an open-end quarter wave coaxial structure.

Best regards,

Wim

358. 80m Vertical over lossy soil

Newsgroup: rec.radio.amateur.antenna
Date: 2007-11-06 22:27:26 UTC
From: ricknj10@hotmail.com
Message-ID: <4730e3c9.29514062@news.optonline.net>
Source record: 34461

Following is a posting similar to what I made on QRZ.com in reply to a guy who was asking what kind of antenna to use out west in the mountains surrounded by tall pines. It summarizes my recent experiences with a vertical on 80 m here in central New Jersey:

Often you will hear the advice "Use a vertical. You will get the low angle of radiation which you need for DX." Be very careful. Although this statement may be true, you could still be disappointed, especially if you are surrounded by trees, and being in the mountains, might have poor soil, which is necessary for good vertical performance. I speak from experience. I have been building and improving my 80 meter vertical recently, with disappointing results. It is a full size quarter wave wire vertical, hung from a rope that goes from my 72 ft tower to a tree. I have 18 radials, 60 feet long. Now that is a pretty good vertical, with no loading coils, with not very much that can be done to improve it except maybe double the number of radials. I am located in central New Jersey on sandy soil. I have used this antenna for the past several weeks, mostly checking it out on DX. In no case has the vertical beaten out the inverted vee at 60 feet. In nearly every case the antennas are virtually identical. Even on DX to VK6 during CQWW this vertical should be kicking major butt, but it is not. Ok, so a few days ago I modelled both antennas with 4NEC2, and I made sure to include the appropriate parameters in the model for my soil conditions (poor). And I overlaid both antenna patterns on the same chart. Voila! There it is, the inverted vee beats the vertical at all angles above 10 degrees, and is equal below 10 degrees. The moral of the story, be careful about making assumptions regarding antenna performance without having an A-B switch! And maybe the other lesson to be learned is how meaningful the antenna modeling programs are.
So my conclusion is that even though the vertical might have the low angle pattern, the losses in the soil do not allow the advantages to be realized. Phased arrays of similar antennas over lossy soil may show the nice pattern and f/b but the absolute value of gain expected may not be realized.

I will save us some time and concede that a vector analysis, which I already know how to do, would work and yield valid results. You and I would not discover anything new in the process. We would agree on the results and not discover any points of disagreement. If you want to divert the issue in that manner, I will agree with any vector analysis that you perform that doesn't contain errors.

Now it's your turn to do a power-density analysis using the data given. Please use the irradiance equation to determine the reflected power toward the source after the external reflection and 1st internal reflection encounter each other. All the data that you need for such an analysis is contained in the example which is the only data that optical physicists had to work with 100 years ago when they couldn't directly measure any phase angles.

It is in the area of the irradiance equation that I might discover any flaws in my technical logic. If you refuse to use the irradiance equation, I will understand completely. Everyone else is afraid of what they will discover.

It would be interesting to see what 4NEC does if you raise the feedpoint,
and centers of the radials, about 10 feet.

Hi Mike,

Experience has born out - and this is supported in both conventional
theory and practice predating Brown, Lewis and Epstein's studies -
that a short antenna is nearly as effective as a full size (albeit
quarterwave in physical wavelength height) antenna. Differences are
in single digit percentages, not tens of dB.

Your example of a 6inch radiator for 20M is suggestive of your own
attempts, perhaps, as you are trying to reconcile poor performance.
There are certainly a world of details to attend to, but once they are
managed, the differences are invisible on the standard S-Meter.

As I've pointed out repeatedly, this is common coverage in the first
30 pages of most texts on the topic of antennas. It relates to the
discussion of the classic short dipole, and by extension the small
loop, and by further extrapolation, any short monopole.

For example, your 6 inch 20M application would exhibit a radiation
resistance of 0.0229 Ohms. The formula for computing this came from
page 28 of the first book I drew down off the shelf - standard stuff
of any book referenced within this newsgroup. When I consider how
much resistance might be found in the transmission line leading up to
this 6 inch radiator, I can easily compute how much power is lost
before it ever reaches it. Dare I go further? Unlike Arthur, I will
trust you to do the math to discover the 10s of dB that are lost to
the combined losses of ground (whose contribution has got to be 3
orders of magnitude greater than the radiation resistance if you don't
plant a field of 100s of radials under that 6 inch radiator).

You don't need to wade through 300 pages following the first 30 to know how abysmal small antennas "might be." They don't have to be, if you are clever, but gilding the Lilly and calling your antenna a Gaussian array is not clever enough by a hundredth. No appeals to arcane theories are required and you don't have to rob the graves of dead white scientists to bolster your discoveries.

There is absolutely nothing spectacular about short monopoles being as effective as large ones - what is spectacular is driving out all the loss that looms in proportion as the size shrinks.

Richard,

I am in basic agreement with the above. Electrically short antennas have extremely low radiation resistance. Low impedence means high currents and greater resistance losses, so that's one source of loss straight away. I did state that the six inches of wire would be inductively end loaded to try and present the same 50 ohm impedence as a full sized antenna at the feed point. Obviously not really a practical proposition. The difference between 5 watts and 100 watts radiated is only going to be a couple of 'S' points on any distant receiver, so as long as the signal is above the local noise level, you can be heard. Small antennas have their place and can be very effective in restricted locations. They will just never be as good as their full sized counterparts. I have no involvement with Art's Gaussian array design, so I can't possibly comment.

I think you might - if you worked it all the way from first transient through to steady state. On the other hand the irradiance equation can apparently lead some people to believe things about the nature of the phenomenon which are not precisely correct.

I saw pretty much the same thing. If you want truly top notch
performance
ground mounted, you have to lay out the wire. Well, unless you are at
the beach or something.. :/
I ran mostly 40m using full size verticals, and even with 32 full
length radials,
I saw mediocre results at best. And I'm on a high rated ground as far
as
conductivity.
When I elevated the antenna to 36 ft at the base is when I finally saw
decent
performance.
Of course, it's not going to be easy to run a full size elevated
ground plane
on 80m.. :(
The only way you are going to see the performance you should is by
coughing up more wire. :(
But according to some I read, 60 will do the trick rather than having
to do
the full blown 120.. Not a whole lot of difference between the two in
theory.
Even elevated at 1/8 wave, a ground plane needs appx sixty radials to
equal
a ground plane at 1/2 wave , using four radials.
And about 120 may well be needed if you really want to equal the
losses of
the high ground plane.
Ground clutter can be another problem, although usually not huge.
But, it's
just another reason why I prefer an elevated vertical if at all
possible.
As far as the modeling, I have to adjust the programs to "very good"
ground
to have it equal what I see in the real world at this QTH.
If they are set to default "average" ground, the verticals get
shortchanged. :(

But on the other hand, maybe that just tells me the ground here is
better
than average, which actually it is... :/ I'm on the gulf coast, and
most of
the area rates a "30" on the conductivity maps.
Thats no sure thing though.. Even though the ground is decent here, I
never had better than mediocre results using a ground mounted vertical
with 32 full length radials. I had very good results with the 36 ft
high ground
plane though. Was like day and night..

There are several serious flaws with this theory. But before commenting, let me say once again that the term "efficiency" has a universally understood and well defined meaning when referring to antennas. It's the ratio of power radiated by an antenna to the power supplied to it. I believe it's being used here to mean something else. If so, its exact meaning should be made clear.

Mike Kaliski wrote:

This shows that the matching network was able to accommodate the impedance that the wires were presenting, not that they were "matching free space".

Including a couple of spread out wires. Of course the efficiency of the system was probably horrible with antennas like the spread wires, due to tuner losses.

You mention the feedpoint resistance of 50 ohms, then talk about the impedance somewhere along the radiator. So you must mean the radiation is taking place from a point where the feedpoint impedance would be 377 ohms if fed there. But there are many antennas which can be very efficient radiators which don't have any point along which they exhibit a 377 + j0 feedpoint impedance. For example, a nonresonant dipole or monopole, which has a reactive component at any feedpoint. Or a moderate sized loop.

> the maximum radiation and coupling occurs at the 'sweet spot' where the
> antenna impedence matches the impedence of free space.

There are some very complex field modeling programs which show the radiated field from an antenna, but you can't assign it to any particular points along the antenna. Every point on the antenna which carries any current radiates a field proportional to the current at that point. (Therefore, your "sweet spots" create a smaller field per unit length that higher current regions.) The sum of the fields from all

points along the antenna add to create the radiated field. This isn't an idle theory, but the basis of antenna operation. Modern computer modeling programs use these principles to calculate patterns which have been demonstrated time and time again to predict the pattern of real antennas with striking accuracy.

Modern methods of antenna design are capable of producing accurate numerical results. Again I'll present my request for a text which details this method. I'd like to see the equations it uses in order to get the same results as traditional methods, and the derivations of those equations.

> I will have to have a trawl through my archives in boxes in the attic to

> have been why these ideas were not promulgated more widely.

Much antenna work was done then, and many of the classical texts and papers were written during that period. Kraus' first edition of _Antennas_ was published in 1950 if I recall correctly, King, Mimno, and Wing's excellent text was published in 1945, and Brown, Lewis, and Epstein published their seminal paper on ground systems in, as I recall, 1937. King's _Electromagnetic Engineering_ was published in 1945. I haven't seen any reference to this alternative theory in any of these.

> As for the heating aspect, because the impedence (resistance if you
> like) of the antenna is constantly varying along its length, the
> application of ohms law will work for specific points along the length
> of the antenna.

The resistance per unit length is constant along the antenna, assuming it's made from one type and diameter of wire or tubing. The current varies along the length, and the loss per unit length = I^2 * R where I is the current at some point and R is the resistance per unit length at that point.

> Calculus and differential equations are needed to
> produce distribution curves for the whole length of the antenna.

They aren't needed to get the approximate distribution on simple antennas like a simple thin dipole. To get the distribution on more complicated antennas usually requires numerical calculation of integrals which can't be solved in closed form.

> For me anyway, visualising antennas operating in this fashion explains
> why electrically short antennas will never be as efficient as a full
> sized dipole (with or without extra twiddly bits bolted on the front and
> back).

This is akin to observing that a rig gets hot when terminated in a mismatched load and presenting it as evidence that the heating is due to "reflected energy". The reason that small antennas are often not as efficient as larger ones is that they usually require much higher current to radiate the same power. This higher current results in greater I^2 * R loss. If the resistivity of the conductor can be kept low enough, the efficiency of a small antenna can be very good. It has nothing to do with "matching to free space" or 377 ohm "sweet spots"

> It covers why SWR is not the be all and end all of efficient
> power transfer and explains how and why directivity arises from multiple
> elements or wavelengths.

This is all easily explained without invoking alternative, and unsupportable, theories.

> I can't claim that any of this is correct, and it may all be a huge
> commercial secret somewhere, but it works for me. But hey, this is
> rec.radio.amateur.antenna and not a PhD course in antenna design.

Indeed it's not. Some of the folks here aren't interested in technical matters, and that's fine -- they can, and I'm sure do, skip my postings. But hopefully there are a few interested in sorting truth from fiction and learning more about fundamentals.

You've gotten up my curiosity. What was the college where you were taught this interesting theory? Was it an engineering curriculum at a university, or was it perhaps a technical school where an attempt was made to explain antenna operation without involving much math? I've been through both systems of education, and found that latter can often get very creative indeed.

Hi Mike,

Not strictly so. There are several vendors of small loop antennas
that are perfectly capable of performance on par with a dipole.
Generally they are sited well remote from the loss of earth on a condo
balcony (presuming there are no eddy current losses to the nearby
railings or dielectric losses in the walls close by).

>I have no involvement with Art's Gaussian array design,

That's OK, no one else has either, and I suspect even Art has never
had any involvement beyond expressing wishes and fantasizing theory.

>You are simply comparing two verticals.

I don't see why you say that. One is mounted on the ground with 16 radials, the other is simply 2 pcs of wire up 60 feet, with 120 degree included angle in my example, although I can change the angle just by typing over top of the 120 I can make it anything I want.
My point was, a lot of people think that if they put up a vertical, even taking care to put a good radial field under it, and they get a low angle of radiation, they have the ultimate single element DX antenna. In fact, when you take losses into consideration a simple inverted vee beats it at all angle over 10 degrees and equals it below 10 degrees. I think that is a pretty significant statement.

> a full length one. . .

You've accidentally stumbled on a well established fact. If not for I^2 * R loss, a short antenna is every bit as efficient as a longer one. After all, if you put 100 watts into *any* lossless antenna, 100 watts is radiated. The only problem is the loss. But it's easily calculated from the current and the resistivity of the material.

> After all, the current at the feedpoint will be just
> the same in both antennas.

No, the current at the feedpoint of a short antenna is greater than in a long antenna for the same power input. (Another way of putting it is that the radiation resistance of a short antenna is less than that of a longer antenna.) If both are to radiate the same power, the short antenna has to have more current in order to create the same field strength from a shorter wire.

> In practice this just doesn't happen, perhaps
> as Art frequently suggests, the accepted engineering texts are wrong (or
> over simplified to make calculation easier). :-)

Nope, antenna texts do just fine. They allow us to separate losses, which we can control to some extent, from basic radiation properties which are fundamental to the antenna topology. The two are often confused, as you seem to be doing, attributing lower efficiency to some fundamental radiation capability deficiency of short antennas. It's not. It's due to loss. All decent antenna texts cover both radiation and loss in great detail and without the need to simplify. Those of us who have, use, and understand antenna texts are able to predict the current distribution, feedpoint impedance, loss, efficiency, and field strength of antennas with very good accuracy.

I'd like to add, use receiving signal strength for comparison. I have a friend who occasionally entertains himself by asking for comparative reports for two antennas. The differences are sometimes striking, especially if the two antennas are described as being very different. But in reality they're the same antenna.

There are at least two other good reasons for using received signals for comparison. First, you can average out the effects of QSB, which can be tens of dB, and can be different or even opposite for two different antennas. And second, you can, with a step attenuator or an S-meter calibrated with a step attenuator, accurately tell just how great the difference is. If someone else truthfully reports a two S unit difference, you don't have any way to know whether it's 4 dB or 12.

I will agree with everything you say about a vector
analysis (unless you make a mistake).

Please let's proceed to the crux of our argument.
Please apply the same irradiance equation that
optical physicists were using before you were born.
Any physics professor should be able to accomplish
that simple task. If optical physicists were in
error in using that equation 100 years ago, please
explain their error.

The average gain of a 1/4WL vertical monopole
with ground-mounted radials is in the ballpark
of 0 dB in all directions.

The average gain of a horizontal 1/2WL dipole
is in the ballpark of 6 dB in two directions.

It is extremely difficult, if not impossible,
for a vertical monopole to achieve 6 dB gain
in any direction.

It is extremely difficult, if not impossible,
for a horizontal dipole to achieve 0 dB gain
in all directions.

Comparing omnidirectional antennas to directional
antennas is like comparing apples and oranges.
Decide which characteristics are desirable and
erect whatever antenna works best for you.

Hint#1: A five-element Yagi makes a lousy net
control antenna.

Hint#2: A monopole with 120 radials has a lousy
front-to-back ratio.

379. Gaussian statics law again

Newsgroup: rec.radio.amateur.antenna
Date: 2007-11-07 01:30:03 UTC
From: art <aunwin@insightbb.com>
Message-ID: <1194399003.906611.152230@o80g2000hse.googlegroups.com>
Source record: 34482

Gentlemen
I go back to this thread again where the challenge was put to existing
radiation laws.
I extended Gauss's law from static to dynamic and used it with
standard
antenna program to obtain Gaussian style antennas. How could that be?
Because antenna programs are based on Maxwells laws and my
extension of Gauss's law proved to be the same as Maxwells law.
The results I obtained were tested on this newsgroup and proved to be
O.K.
So then the plea for mathematical proof. A Dr Davis came on the
scene with no connection to me and systematically went thru the whole
mathematical procedure to confirmmy aproach. Nobody fauled his
mathematical proof and it still survives.
If Maxwell had the same info he would have used Gauss instead of
others
but that was not to be. Gauss's extension clearly shows that radiation
is from a tank circuit form. It also shows (on any computor program)
that for maximum gain of a particular polarity a radiator must not be
parallel etc with the earths surface. The angle that the programs
give
is the resultant vector of all those (curl, fields etc) vectors used
in
analysing radiation. If you review the Gaussian statics law thread
again
you can examine the mathematics involved for yourselves.
So far it has sirvived every challenge including a NEC4 computor
check on this newsgroup. If present radiation theory is to remain
intact then errors must be found in this challenge but none have
proved succesful. So why attack a person who says that maybe
Art is correct? Why not attack the veracity of the mathematics
or what computor programs produce? why not declare what the
capacitance and inductance factors have to do with radiation
per Maxwells laws which is different to what I have shown?
Hams continually ask of new antennas to show me the
mathematics that back the new idea when all know full
well that most hams are not competant enough to even
understand that level of mathematics. Using the mathematics
presented solves the radiation story once and for all, the old theory
does not survive the challenge. So don't go after the "g" station
for stating that I may be correct, prove to him that I am in error
which ofcourse you can't.

Thank you. What you said *was* a help. Maybe without being jolted a bit, I might not be inclined to dig deeper into the subject. Ham radio covers a lot of ground -- so much so that digging deeper is always a selective process.

I've been meaning to get your EZNEC program because it's referenced so often in this group. This pretty much cinches the deal.

Thanks again.

Hi Roy

You are of course an absolute guru of antenna design. You are quite correct in the points you have picked up on, all in accordance with accepted antenna design principles and current theory.

Visualising an antenna as an impedence matching device in the way I described, does allow for a lot of the observed properties to be explained without resorting to much maths.

Waveguides, horn antennas and other designs were explained as being closely spaced dipoles which were brought closer together until they formed a hollow tube. The horn antenna was presented as transforming impedence gradually by varying its physical dimensions. This can of course be demonstrated mathematically.

Anyway, the whole point of any antenna is to transfer power from the transmitter and radiate it into space as efficiently as possible. In order to gain that efficiency, there needs to be an impedence match somewhere. I fail to see why the visualisation method I suggested would yield substantially different results from other accepted methods of antenna analysis. It explains dipole radiation patterns, directivity in multi element or multi wavelength antennas, the reasons why SWR is not the be all and end all, and why a low impedence feedpoint may actually lead to poor efficiency through higher current flow and increased resistance/impedance loss. It doesn't cover off resonance situations or bandwidth of the antenna, but for a quick approximation involving nothing more than ohms law it seems to work pretty well.

Actually it does suggest that increasing antenna conductor diameter would generally be considered a good thing from the point of view of efficiency and increasing the conductor diameter generally broadens the antenna bandwidth, particularly as frequency increases.

Another side effect of my visualisation method is that it suggests that a resonant dipole is the reference antenna against which everything else needs to be measured, rather than a hypothetical point source radiator. From a practical point of view, I think that is perhaps its strongest point. I am not advocating any new physics, just a slightly different perspective on analysing what is happening in the antenna.

Roy, you are a legend and acknowledged expert in antenna circles and I would be a fool to suggest that my methods of visualising antenna performance were even comparable to the predictions and accuracy of EZNEC. I admit I am somewhat in awe of the depth of your understanding on this subject.

It certainly has been an interesting topic to discuss and I thank you for your comments.

Regards

I believe that, unless you have the luxury of relatively unlimited power (like commercial stations), a vertical with radials is not suitable for amateurs. Radials can be looked at as a counterpoise, or in your case, as an inverted V rotated 90 degrees clockwise with 1/2 of the antenna stuck in the sand...and no balun. If I had just guessed, I would have picked to regular inverted V as the top performer of the two.

> Rick K2XT

The only thing is 16 radials is not really what I'd call a good radial
field.
After what I saw here, I don't even consider 32 radials as a very
good
radial field..
But when I elevated the antenna I did the see good DX performance.
It greatly lowers the ground losses to the point just a few radials
will
do the job.
It smoked my dipole on long paths. And as Roy says, I use mainly the
receiver to check, and also I do use an A/B switch..
But I also got plenty of checks on my signal, and of course they
matched the margins I saw on receive. My dipole was not at 60 ft,
but at 36 ft. But to VK land the GP always beat the dipole by
4 S units. And I really doubt raising my dipole to 60 ft would have
been
enough to even the score.
In theory, the ground losses of my GP at 36 ft with four radials
should
have been appx equal to a ground mount with 60 radials.
This on top of the decent ground conditions.
But I also have the advantage of having a clear shot at the horizon
with no clutter in the way. I know the ground/space wave greatly
increased when I elevated the vertical. I could work ground wave on
40m
about 90-100 miles or so. Nearly half way from Houston to San Antonio.
I'd be lucky to do 20 on the dipole.
But another thing... And this may surprise you.. My 40m mobile antenna
is better than my 36 ft high dipole at night if the path is over
800-1000
miles.. Tested it many times to make sure it wasn't a fluke.
I don't know how it would fare on 80m to dx vs the dipole..
Never really tested it. I really don't work that much dx on 80m for
some

reason.. I'm usually working NVIS..

I think I did it thisa way:
Tie both sides of feedline to the center of a short piece of coax.
Tie the braid of the coax to a ground.

put a connector on the other end of the coax and connect it to the radio
(thru a tuner,)

Hi Rick,

Given you did not specify that the "inverted vee" was completely flat
in the horizontal plane, it must be vertical to the degree it is not
flat.

The dominant polarization of an end-fire "inverted vee" is vertical.

Shy of a complete specification, you are comparing two verticals and
they are both lousy.

It is actually comparing two dipoles. One is a so called, misnomered 1/4 W "monopole" but it really is a dipole with several parallel dipole elements buried in the sand. Hams call these antenna elements "radials"; some hams actually regard them as RF ground! Similar thought processes have it that the bread of the host is the true body of Jesus Christ....believe it. In spite of being at ground (zero potential), they radiate but their proximity to earth really decreases their radiation efficieny. Sure, the grounded waterpipes in my basement radiate RF all the time ;-)) The other dipole referenced, the inverted V is a similarly balanced antenna but both poles are up in the air, free to radiate and actually with lobes that have a gain characteristic in some directions (better than small gain in all directions).

A third antenna, not discussed here, would be a real 1/4 W monopole that is truely connected to earth ground and uses no radial conductive elements. Here, the monopole functions as a dipole but 1/2 of the radiation pattern exists as a mathematical image reflecting against true ground (not a good conductor of electrons like radials, merely a zero voltage reference point). Although the mathematical image seems to only exist in theory, the observed physical effects of RF transmission follows the rules of energy conservation and the antenna transmits real RF that can be measured as if it were a true vertical dipole antenna. Now you have seen the real evidence that the host is the true body of Jesus Christ! ...the radials were simply a false religion. The phantom/true earth side of the dipole in the 1/4W monopole

ground plane similuates a real metal conductor, mathematically and physically. The only advantage here is that the grounded monopole is 1/2 the height of the full metal conductor dipole.

Interestingly, whereas radials simulate (very inefficiently) a true ground system, a true ground system simulates that which the radial system cannot achieve very well, but both attempt to acheive the same end. One is ground, the other is more like a counterpoise or misplaced antenna element for a balanced antenna.

This confused example attempts to pull together disparate
characteristics for using ground/radials by extending the problematic
metaphor of an antenna image.

It takes very little effort to answer all objections raised by this
confusion, but it takes very much effort to implement the solution to
this confusion that is the answer = push the radials out to the radio
horizon.

Anyway, the confused example has no bearing on my preceding responses;
the two, the vertical and the vee (as described) are poor performers
below 10 degrees.

Thanks Ralph - very interesting reading. My mid 80s vintage RS20A seems to
be falling out of regulation under the ~15A load of my HF xcvr during xmit.
Fortunately for me, I homebrewed a PS from an article titled "An RF-Proof
30-Amp Supply" (ARRL Handbook, 1988-89) that works much better. The output
doesn't start to fall off until the load approaches 27A (using 4 x 2N3771s).
With the exception of the outer cabinet itself, it's entirely homebrew...
fabricated the chassis, made my own photo-etched PCB, and rewound a 750VA
transformer.

Unfortunately the Earth is largely covered with dirt. It's unclear to me how you "truely connect" to it. Radials provide the lowest loss "connection", but you seem to know of a better way. Please describe it for us.

Even if you could make a zero-loss connection to ground (and a large radial field comes close enough for nearly all practical purposes), that dirt still doesn't provide the "mathematical image" of a perfect ground plane. The net effect of the ground's finite conductivity is that the low angle part of the radiation is absorbed in the dirt, heating the earthworms and resulting in a radiation pattern that doesn't resemble a free-space dipole (or monopole over a perfect ground) very closely at all. These effects can be clearly seen with any modern modeling program including the free EZNEC demo. Example file Vert1.ez uses a "MININEC-type" ground which does provide a zero resistance "connection" to ground, something you can approach but not completely accomplish in practice. Compare the pattern of this model to the same one with a perfect ground (superimpose the two on the 2D plot so they're drawn to the same scale) to see how poor an approximation dirt is to a perfect image plane.

I don't understand that at all. But as you pointed out a while back, I'm a ham with an American Extra Class license, so I know I can't be expected to understand anything very complicated. (Worse yet, I took the exam 44 years ago, so 9/10 of what I knew then is obsolete, and I've forgotten the rest.)

Much more likely, it's a scam:
"You only need to send us $100 to get started, and we ship the product
to you."
"There's been a small snag, and we will need another $100 for
licensing."
"An official is giving us a bad time, and we need $1000 to make sure
that he cooperates."
If it was ligit, why advertise it here, when it has nothing to do with
antennas?

It's certainly a scam. The only thing open for speculation is which one. One of the scams requiring a "representative" in another company involves purchasing goods with stolen credit card numbers and having them shipped to the "representative" aka the mark. The mark ships them to the scammer in a country with lax law enforcement, with the promise of a big commission or whatever other promises are necessary to keep him/her on the hook. Of course the commissions never come, the mark is out the substantial shipping charges, and when the Visa guys come knocking, the mark's house, not the scammer's, is where they'll come. One of the network exposï¿½ programs followed a package clear to the scammer in, as I recall, Niger. Part of bait keeping the sad middle aged man on the hook were pictures of a sexy young lady with appropriate suggestive messages and promises of marriage.

I get about a half dozen of these (offers to be a "representative", that is, not promises from sexy young ladies) among the 200 or so spams I receive every day. Anybody interested in hot deals just let me know. Penis enlargement is currently the runaway popularity leader, but there's quite a bit of variety.

Zero or six decibels with respect to what reference, Cecil?

If that reference is an isotropic radiator, then note that a typical 1/4-wave monopole and buried radial ground system used by commercial, non-directional AM broadcast stations has an h-plane gain of about 5 dBi. This value has been confirmed by thousands of groundwave field strength measurements of such systems going back 70+ years. Also note that the gain of this monopole over a perfect, infinite ground plane would be only 5.15 dBi, so a broadcast radiator is quite good indeed.

And -- a gain of more than 6 dBi is produced by broadcast monopoles whose height exceeds 1/4-wave sufficiently. For example, the h-plane gain of a 1/2-wave broadcast monopole system is about 6.6 dBi (6.8 dBi over a perfect ground plane).

When the infrared EM energy encounters the earth,
it is transformed from EM energy to heat energy.
Before that transformation, it is just another
set of EM waves differing only in frequency from
any other EM wave, e.g. RF and light.

Stefan, do you have those religious fantasies often? You know we do have drugs now, that cure those.... Drugs are preferred over the old tried and true cure, which involved piles of dry wood, pubertal girls, and combustion...
Anyway; Hey I enjoyed your discussion... Now back to the task at hand...

Rick, to improve DX performance on a quarter wave vertical over a reasonable radial field I have to go to a dipole at 100 feet, or to one of the high inverted vees, 120 & 150 feet.. While I no longer have a horizontal antenna below 100 feet for 80, when I did the quarter wave vertical shone on DX compared to the lower horizontal antennas.. Secondly, 18 radials just will not do it when you care to send the very best <hallmark>... An absolute minimum of 30 is needed, and for long dx 50+ is going to be neeeded... By the time you have the radial count up to the 50-60 range you have pretty well maxed out any major improvements until you surpass a 100...

Now, there are those who like elevated radials <Christman> and those who hate em <Rauch>.. I have to say that my personal experiences on 160 is that 10 or 12, 1/4 wave and tuned, elevated radials works - but they are a pain to keep in the air (in the woods), and tuned, and working... I worked Heard Island with the elevated array on 160...
My current 160 ground mounted vertical array has well over a hundred radials of varying lengths and seems to work (G3 from the black RF hole of Michigan on 100 watts while the amp was warming up two nights ago, so it plays reasonably well)
Now a dipole or vee at 130 feet is simply not going to work on 160, period... Oh yeah, you can wow the guys at 700 miles with your NVIS signal, but you will get trampled in a dx pileup...

So bottom line, even on 80, is that you need to either go to an elevated array as others suggested, or you need to improve your ground radial count - at which point the vertical will shine over a low vee at 1000 + miles...

Roy, similarily in my profession; I know that half of everything they taught me is wrong, they just won't tell me which half!

cheers

Sorry, I had a senior moment - should have been dBi.

I was speaking of the typical ham radio 1/4WL monopole.
EZNEC's VERT1.EZ is an example of such an antenna with
a maximum gain of about 0 dBi.

The point was that the average 1/4WL amateur monopole
doesn't equal the maximum gain of an average 1/2WL dipole,
much less the gain of a more directional antenna.

Expanding on this for S. Wolfe, even if a point connection having zero resistance to earth potential existed at/near the base of a vertical monopole, a monopole using that ground reference would be a poor radiator.

This is because the r-f ground currents that need to flow back into the antenna system first would need to travel through the lossy earth from distances up to 1/2 wavelength from the monopole, to reach that perfect ground connection.

The function of the buried radials is to provide a low-resistance path for those ground currents, which means that they have to be collected as closely as possible to their sources in the earth (eg, within a disc having a radius of 1/2-wavelength around the monopole).

A benchmark field study in 1937 by Brown, Lewis and Epstein of RCA showed that about 120 buried radials each at least 1/4-wave long enable a groundwave field to be radiated by a monopole that is within a few percent of that over a perfect ground plane. Ground conductivity at their test site was no better than 4 mS/m. Their test frequency was 3 MHz.

And NEC shows that such maximum gain occurs at some angle above the horizontal plane, maybe 20 degrees? NEC also shows zero relative field in the horizontal plane, and very low values below elevation angles of 10 degrees or so.

But note in the graphic linked below that for broadcast stations using 1/4-wave monopoles, nighttime skywave coverage in the range of 400 to 1,000 miles is provided by radiation in the range of 1 to 20 degrees elevation. Both theory and practice show that monopole radiation for these conditions could not be as given in a NEC analysis showing the field at an infinite distance.

http://i62.photobucket.com/albums/h85/rfry-100/TermanFig55.jpg

> The point was that the average 1/4WL amateur monopole
> doesn't equal the maximum gain of an average 1/2WL dipole,

It could get very close to it though, with the necessary buried radial system.

Well I have gone and done it, I proved you tell lies
The mathematics are on the web in the archives
See thread Gauss's static law and my posting
yesterday on the subject. Now hams have got
what they asked for but they are not equipped
in mathematics to sustain the challenge to
present day antenna theory. Note that you
are not alone but as a broadcast engineer
your thirty year experience consisted of the
same experience day after day.
But you are not alone, not one ham on this
newsgroup have sufficient knoweledge in mathematics
to follow unless taken from a book.
You lied about the mathematics not being available
and the rest did not help you or follow on with
piling on which is normal for a newsgroup.
Either that or they do not read your posts.
So Mr broadcast engineer go to your corner and sulk
and ponder how to prove the mathematics wrong.
As I said before you are a lier and now I have
supplied the proof and there is nobody here
that can assist with the math.

Most hams who strive for maximum radiation that is horizontally
polarised place the radiator parallel to the earths surface.
That is an example of herd mentallity.
When the vectors of radiation fields and "curl" are summated
the resulting vector is NOT along the axis of the radiator.
For maximum horisontally polarised radiation it is this
vector that must be parallel to the earths surface.
By the way Maxwell confirms this but hams chose
to ignore it.
Yup, herd mentallity!

Even a vertical DLM antenna can be a challenge, depending on any certain individuals property/lot, neighbors and other factors ...

At 20m on down this becomes MUCH more practical ...

And, most physically short antennas introduce degraded performance--the DLM being a notable exception.

>we get all that radiant heat from 93 million miles away? Sincerely, and

Hi John,

Is the volume of space immediately to the left of planet Earth as warm as planet Earth? A balmy 13ï¿½ to 17ï¿½ C?

Same source, the sun.
Same distance, 93 million miles away;
Same power (sic), energy per unit time;
Same propagation, speed of light without obstruction;

Same heat? Not even close - even when accounting for and removing the core temperature of Earth. A rather absolute chilly of 3ï¿½ K.

Substitute the Moon by placing it to the left of Earth. Is it as warm as planet Earth? A balmy 13ï¿½ to 17ï¿½ C?

Same source, the sun.
Same distance, 93 million miles away;
Same power (sic), energy per unit time;
Same propagation, speed of light without obstruction;

Same heat? Again, not even close. A rather toasty 107ï¿½ C!

Two examples in proximity to Earth, and yet both seem to exhibit that the Sun does not propagate power linearly. What could possibly account for this error when the path is unobstructed and the Sun's radiation is uniform? Even more quixotic is that the smaller load of the Moon exhibits a higher dissipation of radiation (and has virtually no core temperature effect to elevate that result).

Well, albedo has something to do with all three; but that is load dependant and has nothing to do with energy per unit time from the source. Insulation has something to do with all three; and that too has nothing to do with energy per unit time from the source.

So, is the Sun selectively powerful (like a god)? Is the Sun like some really, really huge radiant lamp (the kind with a toaster wire wound like a slinky in the middle of a radar reflector)? Point the radiant lamp at you, and you get toasty, step aside, and the air that replaces your volume does not - hmmm. Put a pane of glass in the same region, same chilling result.

Something going on here and there seems to be only one commonality to power - the function of the load in the presence of energy.

Energy propagates much as we expect it does; power - well, not always (hardly ever).

Just to note that the URI test report showed the standard DLM on 3.5 MHz to have about 2.33 dB less gain than the Navy's reference monopole. That means that its groundwave field was found to be about 59% that of the reference monopole.

Some might consider the performance of that DLM antenna to be "degraded," compared to a standard 1/4-wave monopole using the same r-f ground.

You crack me up too
I was just reading all your posts to John E Davis on the
gauss statics law all over again.
All handwaving about mathematics but you presented
nothing that over rides his math.
No math or is it no mass?
You got your adults degree based on your journeys in the Navy
but that didn't provide you with a mathematics regimen
to fault Davis did it?
You never wrote anything that wasn't "fuzzy"
Whant to prove my initial post in error
or return to your fuzzy logic suitably scrambled
so that it cannot be deciferred?
Try proving my initial post on this thread is in error
but then you can't so you will resort to handwaving.
Yes, Krauss, Maxwell Gauss and many many others support it
but you, you are not equipped to oppose

Hello, and the above statement is simply not true as any undergraduate textbook in electromagnetics will point out. Transmission lines, for example, be they 60 Hz or at RF due in fact transmit power from source to load. At any point along the line the average power is given by 1/2 the real part of the product of the voltage and complex conjugate of the current. Voltage and current contain their respective components of travelling waves in both directions (source-to-load and load-to-source). Of course the transport medium doesn't have to be a transmission line - it can be free space, say from a transmitting antenna to a receiving antenna.

I have no idea how many of those in our ham hobby have taken any courses in electromagnetics (traditionally called "fields" by undergrad EE students). Such courses are part of an undergrad EE program and if you major in electrophysics (as I did) at the grad level you delve much deeper into the subject. Sincerely,

You guys heard me gripe about the difficulties of a fan dipole, especially with close element spacing, last week. I spent some more time cutting and pruning and rehanging and just gave up because the damn thing never had a resonance fall anywhere in the 40M band.

I just obliviated all the issues by getting rid of everything except for the 135foot element, and replacing the feed coax with 450-ohm ladder line on the back of my antenna tuner (Ten Tec 277). The antenna loads up very nicely on all the ham bands, and although the patterns on the upper bands are certainly different than a dipole, they were just fine for doing some DX'ing yesterday. Lotsa fun!

I had previously worried about the gotchas of routing ladder line into my shack but it really wasn't so hard.

Hi John,

I majored in English. Yet and all that intellectually crippled, I found you couldn't respond to heat (the expression of power by your own choice) being the dissipation of energy in a load, and that energy is the entity that propagates - not power.

As the topic has migrated away from your original thesis of heat and the sun towards fields; I, as an English major, am at a loss to discover the correlation that resolves how fields can resurrect the missing heat in an Earth equivalent volume of space, or provide the surplus heat found in a smaller volume of the moon - all from the same source of those fields, the sun.

Are fields selectively powerful (like a god)? Do the fields of some really, really huge radiant lamp (the kind with a toaster wire wound like a slinky in the middle of a radar reflector) propagate differently? Point the radiant lamp at you, and you get toasty, step aside, and the air that replaces your volume does not - hmmm. Put a pane of glass in the same region, same chilling result.

The closest mechanism of the transfer of power (heat as you originally premised) is found in Phonons, not Photons (aka sunlight, again, the source of your choice). Phonons exist only in physical materials (loads). Phonons are what is responsible for the flow of heat (does this metaphor of power movement sound familiar?), In fact, Phonons are specifically and explicitly power moving in a material. Again, the commonality of this discussion is found in load specific energy (photon-phonon) interaction as power and uniquely heat (your terms).

Phonons also exhibit field-like characteristics (there being optical phonons and acoustic phonons that provide for both transverse and longitudinal waves). In addition, once a phonon hits the margin of the material it is migrating through it reflects or transforms. However, in the transformation heat is left behind and energy moves on (that is how your thermos works in the face of fields too).

I can provide you with pdf material from "Electron phonon interactions : a novel semiclassical approach," Rose, Albert, to aid you in this avenue of power transfer if you care to examine it. Other references

(sans pdf copy in the short term) can be made available too. I can probably point you to resources in your own lab that amplify along these lines of phononic interactions (I think I heard one presenter from down your way talk about aerogels).

Oh I believe that there are quite a few who memorised what was taught
and what was in the books but now they are getting older and the
memory is failing where they didn't understand the basics.
Since you may be younger and have taken the EE course. Try adding a
time varient
to Gaussian statics law and thus show how it equals Maxwell's law.
But them you may be relying on memory as well and bypassed
mathematics.
Richard has come a long way by doing that and nobody is equiped in
mathematics to call his bluff.
Things were like that when I was in the military. Don't ask why
just put it into the memory box and follow orders. If you can't
remember
then follow the rest of the squad. Doesn't that sound like ham radio?

So no mass and bluffing shows the error of
>Rr = 80 ï¿½ piï¿½ ï¿½ (length/wavelength)ï¿½
?

No one doubts that from you Arthur. Do you know what mathematics is?

To this point, your theories lack equations, and lacking equations
they lack results. You often fail to provide the minimum enumerated
characteristics of
1. frequency;
2. wavelength;
3. angle;
4. gain;
5. resistance;
6. reactance;
7. Q;
8. voltage;
9. current.
Yet and all, you claim to have a theory of RF that lacks values for
each and everyone of these specifics that are rudderless in your brand
of math without equations. True, you line up all these words in all
the possible combinations and permutations (and sometimes even spell
them right), but not always in coherent sentences and rarely
punctuated correctly. Enlarge your word palette and you may one day
script "Hamlet" through the same random process.

However, I am glad to see you still read my comments! So that
inspires me to happily slog on through your murky postings. ;-)

Forge on for Queen and Country!

Hi Bob,

At least one feedline conductor is a miserable horizontal radiator.
However, with this excellent performer, don't look for cavities in the
oral opening of an Equine.

My experience in MS (clay soil) comparing a dipole (nearly flat-top) at
about 90 feet to verticals is that the verticals nearly always win for dx.
(this is on 3.5 MHz).

However, I usually put down ~50 1/4-wave radials for the verticals.
I would definitely increase the number over 18.

My qth is also surrounded by a large number of large pines. In fact
the verticals I compare to are wires supported by the trees.
I have no idea how much they affect the signal, but verticals still
outperform dipoles for dx at my qth.

Do you have other metal objects or ground clutter (houses, etc) near to
the vertical? What was the feedpoint impedance of the vertical?

Yes. Ktaus says: "Antennas convert electrons to photons or vice versa."

Neither volts nor amperes are radiated. Associated electric and associated magnetic fields are radiated.

Fields are force linkages of unknown operation.

Power exists in a radiated wave from an antenna considered as a point source, and at a distance it may suffice to specify the power density or Poynting vector magnitude (power per unit area) from the antenna.

Currents flow out on an antenna but end there. The fields associated with them keep on going. It takes real energy, volts x coulombs/sec., in an antenna to cause radiation. (Watts=volts x amperes, and amperes are coilombs/sec.)

Reciprocity rules in an antenna. An antenna intercepts radiated fields and extracts real volts and amperes from energy in the radiated fields. The ability of a receiving antenna may be called its aperture efficiency.

Best regards, Richard Harrison, KB5WZI

Hello, Richard and all.

With regard to power (be it from the sun or some other source of energy), strictly speaking I would agree that what is transported is energy. Physicists and engineers usually include the ability to do work (as well as the work itself) as part of the concept of power. For example, we can have "available power" at the terminals of a receiving antenna even though the antenna is not connected to a dissipating termination. Radio/antenna engineers and physicists also use the concept of "power density" (usually in units of watts per square meter) at some distance from a transmitting antenna. We then speak of an antenna having an effective "capture area" that can extract a portion of this power from incident electromagnetic waves.

In this regard we speak of power being transmitted through a medium. If we clock energy flow across a boundary for a specified time then the quantity of energy divided by that time represents power flow across the boundary.

With regard to the sun/volume question I'm not qualified to answer that. The earth still retains its primordial inner sources of heat and other forms of energy as manifiested in erupting volcanoes, geysers, and deep sea thermal vents. Of course these are in addition to radiant energy from the sun. Sincerely,

How does distributed capacitance harvest the energy given
in sino soidal form and later release it in the same form
that it was harvested in?
Same question, but now look at distributed inductance and
how that works!
Distributed resistance is easy, it changes the energy to heat,
stores it and releases it according to its time constant but
the books don't tell me.about the other things!
Like the time constant of distributed capacitance

Hi John,

You might be interested in the work of Debra R. Rolison, Ph.D. Naval Research Laboratory -- Surface Chemistry Branch. The lead-in would be the medium of aerogels where her presentation that I attended nearly 5 years ago was called "The Importance of Nothing in Nanostructured Materials." You will learn from her that power in the form of Heat (not many other forms left) does not transmit through aerogels. However, for her research, that is one of those "People" magazine kind of qwik-facts where her work investigates to a greater depth. She is quite conversant and has a vice-like grip on the topic.

Ask about Phonons insofar as how Power moves through a medium.

The unit of power is the watt. If power is being
transmitted, the transmitted power would have units
of watts/sec or joules/sec/sec. What would be the
physical meaning of joules per second squared?

Dunno..I can't remember W8JI using elevated verticals..
He may be seeing a large number of people that
run elevated, but don't use enough radials for the
height in wavelength. Most don't, and then wonder
why they don't play as planned.. :(
Most 160m elevated verticals are still going to be low
to the ground as far as wavelength.
Sixty feet is only 1/8 wave. To equal a GP at 1/2 wave
requires appx 60 radials. This also equals 120 radials on
the ground. 1/4 wave up requires appx 8-10 or so radials
to equal the same ground loss.
On 160m, many think they can elevate a vertical 20
ft or so, and use maybe 4-8-10 radials to get good
performance.
It just doesn't work that way. At such a low height in WL,
they need almost as many as a ground mount.
On 160m, a ground mount is really more practical as
everything is large. It will be a lot easier to plant
60+ radials on the ground than it will be to raise the
vertical to a decent height. This might apply to 80m
also for most people..
But on 40m, it's not hard to set up a decent GP,
and my 32 ft whip was fully self supporting.

> Now a dipole or vee at 130 feet is simply not going to work on 160,
> period... Oh yeah, you can wow the guys at 700 miles with your NVIS
> signal, but you will get trampled in a dx pileup...

Heck, W8JI ran a 160m dipole at 300+ ft.. The verticals still
won as a transmit antenna to DX. I think he uses 60 radials,
unless he's added more since that time. I forgot what his
vertical is.. A tower of some fairly tall height... It ain't no
typical ????
brand multiband dummy load on a stick... :/

>?

You asked for a simple, one-sentence equation you could prove wrong
with mathematics. Feel free to fill in the variables and show how the
solution is wrong. [Hint: the same formula can even be found in a
book you own, page 12 of chapter 2, of J&J, if you haven't colored
over it on the page.]

Note, that if you prove this wrong by your mathematics as you said you
would, you simultaneously impeach your only reference book that you
have used to prove your theory. Quite a paradox isn't it? I don't
think Johnson and Jasik ever show that mass and bluffing like yours
proves the error of their own work.

Assuming the feedpoint impedance on 40m is somewhere
around 35 ohms, the 40m SWR on the 450 ohm line would
be around 13:1. Assuming the feedpoint impedance on
20m is around 1200 ohms, the 20m SWR on the 450 ohm
line would be around 3:1. You probably should make
the ladder-line somewhere around an integer number of
1/2 wavelengths long on 40m and your tuner should be
able to handle the rest. You will have some common
mode current in the system that could cause some
radiation and losses from the ladder-line.

Feynman's words are better. "A photon goes from
place to place. An electron goes from place to
place. An electron emits or absorbs a photon."

Antennas do not change electrons into photons.

I've even read that electrons repell photons no less!
There are lots of fairy tails in radiation and yet scientists say
that the matter of radiation is unknown. Obviously they do not
patronise this newsgroup. Probably all lurking in Newtons mechanical
group.
Cecil have you heard that one about static particles that rest on the
surface
of a radiator? Not sure what they are waiting for.
Looking for conjugal rights maybe if the right photon comes along

Egad, someone's ignorance is showing. Quoting from "Optics", by Hecht - writing about electromagnetic waves:

"It's possible to compute the resulting force via Electromagnetic Theory, whereupon Newton's Second Law (which maintains that force equals the time rate-of-change of momentum) suggests that THE WAVE ITSELF CARRIES MOMENTUM. Indeed, whenever we have a flow of energy, it's reasonable to expect that there will be an associated momentum - the two are the related time and space aspects of motion. As Maxwell showed, the RADIATION PRESSURE equals the energy density of the magnetic wave." (emphasis is Hecht's, not mine.)

You may be interested in the paper linked below, which reaches
a very different conclusion, verified by field experience.

NEC models of this system in the broadcast band with the radials elevated 20
feet show gains equal to those using a classic broadcast buried radial
ground system. And if this true in the broadcast band, I expect it is true
for 160 meters.

The only problem is I see no direct comparisons to a normal set
of buried radials. Only that they were able to meet the "minimums"
required by the FCC. I would be curious to see how well the 6 radial
setup would compare to a non crippled set of 120 radials.
It's interesting, and I'd already seen it, but I'm not really
convinced
thats it's equal to 120 radials in the ground.
Certainly usable though..
I've seen plenty of tests done by amateurs that pretty much swings
in the other direction. In fact, being my 40m GP was on a
push up mast, I was able to try it with it's four radials, but at
lesser heights. It did not work near as well at 1/8 WL, vs it's
normal 1/4 WL height. And in terms of wavelengths off the ground,
it had an advantage over the 160m scenario.
Also, modeling might show them equal, but that still doesn't really
convince me until I see it happen in the real world.
I've seen a lot of hams have very mediocre results doing pretty much
the same thing on 160 and 80. I remember one in particular that
got fed up and replace it with a set of normal radials on the ground.
Greatly improved his performance.
I guess I'm a firm believer in the loss per number of radials vs WL
I often quote... :/
So far, I've never seen any indication they are off by any great

degree.
BTW, I still prefer the elevated vs ground mount. I'm just not as optimistic about the number of radials required to equal 120 in the ground as they are. :/

Roy Lewallen wrote:
"Those of us who have, use, and understand antenna texts are able to predict the current distribution, feedpoint impedance, loss, efficiency, and field strength of antennas with very good accuracy."

Yes. It would be satisfying to know how fields exert their invisible forces at a distance but we can predict repeatably their results and that is the fields` importance.

Terman wrote on page 1 of his 1955 edition of "Electronic and Radio Engineering":
"One half of the electrical energy contained in the wave exists in the form of electrostatic energy, while the remaining half is in the form of magnetic energy."

On page 2 Terman wrote:
"The strength of a radio wave is measured in terms of stress produced in space by the electric field of the wave, and it is usually expressed in microvolts per meter."

Obviously, due to the 50-50 distribution of energy in an EM wave, either constituent is sufficient to describe the wave.

Also on page2:
"The strength of the wave measured in terms of microvolts per meter of stress in space is also exactly the same voltage that the magnetic flux of the wave induces in a conductor 1 m long when sweeping across the conductor with the velocity of light.

On page 866 Terman wrote:
"In such a situation (actual antenna broken down into very small increments) the field radiated in any particular direction is then the vector sum of the fields radiated from the individual doublets (increments) taking into account the magnitude, phase, and space orientation of the component fields produced at a distant receiving point by each doublet."

Kraus calls the summation of the contributions of incremental elements of a conductor the "Moment Method". See page 461 of the 3rd edition of "Antennas".

Hi All,

May I come in with some comments from a somewhat different perspective concerning where the reflected power
goes, or where it doesn't go?

Because I'm not particularly adept concerning solid-state tx, this discussion will involve only tube tx with
pi-network output circuits. We'll assume that when the tx has been adjusted to deliver all its available power
into a resistive load, the output resistance appearing at the output terminals of the tx is equal to the load
resistance. For those who may disagree I refer them either to Chapter 19 in Reflections 2, or the May/Jun
issue of QEX, where I report the results of measurements that prove the statement to be true.

Consequently, we'll begin by adjusting the tx to deliver all its available power into a 50-ohm resistive load,
a real 50-ohm physical resistor. Next, we'll change the load to be the input of a 50-ohm lossless transmission
line terminated with a 3:1 mismatched load. What impedance will the tx see? Until we specify the actual load
terminating the line and the electrical length of the line, the tx may see any impedance appearing somewhere

on the 3:1 SWR circle of the Smith Chart. What will happen when the tx sees this mismatched load? First,
because the 3:1 SWR results from a voltage reflection coefficient of magnitude rho of 0.5 (and a power
reflection coefficient of 0.25), this mismatch will cause the tx to reduce its output to deliver only 75
percent of the power delivered into the matched 50-ohm load.

Will the reflected power enter the tx and cause heating? Or will it cause cooling? The answer is that the
reflected power does not enter the tx. So what does happen?

By changing the length of the transmission line at will, we can cause any impedance found on the 3:1 SWR
circle on the Smith Chart to appear at the input terminals of the line. Let's assume the impedance found there
is 50 ohms x 3 equals 150 ohms. This impedance is a lighter load than the original 50-ohm load, so the plate
current will be less than with the 50-ohm load. However, the reflected power did not enter the tx, it only
caused the 150 plus j0.0-ohm impedance to appear at the line input.

Now the important point: The tx would have responded in exactly the same manner if its new load had been a
physical resistor of 150 ohms instead of a 'virtual' resistance of 150 ohms resulting from voltage/current
relationship appearing at the input of the line.

Let's now consider if the line-input impedance is 50/3 ohms, which equals 16.667 ohms. In this case the new
load is lower than the original 50-ohm load, resulting in overloading the tx, causing the plate current to
rise above the rated level, thus causing overheating. But the overheating was caused only by the increase in
plate current resulting from the lowered load resistance, not by reflected power entering the tx. Again, the
same condition would have occurred if a physical resistor of 16.667 ohms had loaded the tx instead of the same
value of virtual resistance appearing at the line input.

Now a third case important to the issue, that in which the impedance appearing at the line input is 50 plus
j57.738 ohms, which also appears on the 3:1 SWR circle. In this case the 57.738 ohms of inductance simply
detunes the pi-network away from resonance, causing plate current to rise, increasing the temperature, but
still reducing the output power to 75 percent of that with the 50-ohm load. And again, precisely the same
result would occur if the new load had been a physical resistance of 50 ohms in series with a physical
57.738-ohm inductor. (It should be obvious that a simple readjustment of the plate capacitor of the pi-network

would return the network to resonance, with the result that the operation of the tx would be identical to that
when loaded with the 50-ohm physical resistor.

The purpose of this commentary is to show that reflected power does not enter the tx, and that the tx cannot
distinguish between a 'virtual' load impedance appearing at the input of a mismatched transmission line and a
physical load comprising a resistor in series with an inductor-the results will be identical in either case.

So Radio hams, professional and amateur. Does distributed store
energy like other capacitors or is it an animal by another name?
Does it store photons for later distribution of radiation?
Do photons eat the electrons while they are being stored by the
capacitor
Do the electrons jump up and down because they know an inductance is
ahead?
These questions are very important in determining what radiation is
all about.
And yes I hear waves are often mentioned. Is this the three
dimensional

wave that is created in the pond when the static particles fall off
the antenna
in a circular type pattern? Antenna books say the pattern is a figure
eight!
How can that be? When the energy removes itself from distributed
capacitance
do the photon march along the antenna in an orderly fashion? or do
they rush out
as if the movie in the capacitor is over? Last of all has anybody seen
a photon
and photographed it? I suppose if you believe in ghosts then you could
well
believe in photons that float in the night. You can't see them but
there
really is a chill in the air. So back to the original question,
What does distributed capacitance do with the oncomming sino soidal
wave?
Does it let it through unharmed so that we have a time varience that
is needed
for radiation per the radio books?
Art

>
> I have no idea what you're talking about, Cecil.

I know and you are not alone. I was taught about
power transmission in college but it was actually
energy transmission they were talking about. The
power company doesn't charge me for power - they
charge me for KWH, i.e. energy.

Consider a Bird wattmeter in a flat transmission
line. It is at a fixed point reading watts. Are
the watts moving? The Bird is displaying joules/sec
passing a fixed point. The joules are certainly
moving but are the joules/sec moving? As you noted,
it seems that if the joules/sec are moving then the
joules must necessarily be accelerating.

You can measure the number of cars passing over
a bridge in one hour and write that number on your
notepad. The cars are moving but is that cars/hour
measurement written on your notepad moving? If so,
where is it going?

Your intuitive theories may not support this, Arthur, but haven't you noticed that your linear, dipole antennas (whether "short" or 1/2-wave) transmit and receive very poorly in the directions of their longitudinal axis? In fact, radio direction finders make use of this proven reality of radiation physics.

How do you explain this, if you believe that the radiation pattern/gain of a dipole is not very low in those directions, as in the nulls of a figure 8, and as easily measured for these antenna configurations on a good test range?

Please post your supporting math(s).

A herd is by definition relatively unstructured. However, there may be one or a few animals which tend to be imitated by the rest of the members of the herd more than others. An animal taking this role is called a "control animal", since its behaviour will predict that of the herd as a whole. It cannot be assumed, however, that the control animal is deliberately taking a leadership role. Control animals are not necessarily, or even usually, those that are socially dominant in conflict situations, though they frequently are.

Source record: 34320

We are setting up an active Amateur Radio station at Colorado's "Wings Over the Rockies Air and Space Museum" here in Denver. We are currently installing a Hustler 6-BTV Vertical on the very large metal roof of the hangar which is about 40 to 50 high, but are having difficulty with proper tuning.

We initially assembled the antenna with the following dimensions (in inches) according to the manual:

A = 1, B = 1-5/8, C = 1-1/16, D = 1-1/2, and E = 1-1/2

The mast and metal roof are well grounded and show continuity between all panels. The mounting bracket had to be placed 24" above the roof and, although the mast/bracket/roof are grounded and bonded, we have placed a grounding cable from the mounting bracket to the roof.

We have also made the 6" RF choke coil, however, SWR measurements are not significantly different with or without the coil OR with or without the ground cable.

Initial measurements with an MFJ Antenna Analyzer show that the lowest SWR measurement is significanly below each of the band segments.

For instance, our measurements on the 10-meter band were:

SWR dipped to 1.5:1 at 25.9 mHz with the 72" tube fully shortened.
SWR dipped to 1.6:1 at 25.8 mHz with the 72" tube extended 1",
SWR dipped to 1.6:1 at 25.7 mHz with the 72" tube extended 2",
SWR dipped to 1.5:1 at 25.6 mHz with the 72" tube extended 3", and
SWR dipped to 1.5:1 at 25.4 mHz with the 72" tube extended 4".

According to those measurements we would have to cut over 30" from the 72" tube to get to a tuned frequency of 29 mHz.

That does not seem right, so I would appreciate any comments or suggestions to help make this antenna work.

73,

KB6CC

An alternative way to view your antenna is a large metal ground plane with the vertical mounted on it and fed 24" up from the base. In that case, resonances would be lower than expected, explained by the vertical being 24" longer than design.

I'm not sure where else to ask this question, but I guess since this group deals with antennas then maybe you guys are familiar with this. This is regarding HDTV broadcast:

"Because of the 6 MHz. channel bandwidth allocated, each channel will only support a data rate of 19.2 Mb/sec."

How is 19.2Mb/sec calculated?

Thanks!

Ofcourse there is no radiation off the ends. What ever is sitting on
the antenna
can only fall off one side or the other. As far as the math goes you
are not
conversant enough with math to get involved. You could redeem your
self by
pointing out the deliberate mistake made by Dr John E Davis and become
an overnight
guru. Just think up another lie nobody will challenge you!

> - Show quoted text -

Oh my.All this discussion to help out a newby. So many differences, so many arguments
it is enough to push a newby away from ham radio.
Let's keep it simple.An antenna is just a pendulum with two energy storage tanks per cycle.
Each energy tank releases the same amount of energy for the other energy tank to catch and store before he sends it back.
They call these energy tanks distributed capacitance and inductance and they are only equal in size
at one wavelength.Anything different from a wavelength and one side releases more energy
than the other side so you must come to the aid of one side or live with the consequences of imbalance
which is measured by SWSR, that is the pendulum swings more one way than the other.
Now you have two energy sources throwing energy at each other ,harder and harder
such that the transmitter or the onlooking manager starts to get all sweaty and close to a heart attack.
If the energy sources want to stay on the team and the manager doesn't want a heart attack then every body shuts down until they find a way for the pendulum to swing smoothly backwards and forwards in a friendly manner.
See, antennas are not all that hard to understand if you have the time to do things right. Forget about photons and reflections which everybody is arguing about, just make sure that your antenna and transmitter is happy by keeping the swr down as it is this that disturbs the operation and nothing more.

Interesting. So in the case of amateur radio it is the ARRL who
is the control animal
because they are socially dominant. Very good!
I always saw it as a group of lemmings where each animal has his
nose stuck under the rear of the animal in front, often called
brown nosing, in a pecking order.
So what's in it for ARRL to keep angled radiators a secret by
, keeping it out of the handbook, did they copy write it so
they can take the secret to their graves?
Best regards

Art, I suggested a few weeks ago that you could make a killing in writing humorous lines for either Jay Leno
or Dave Letterman. But I guess you had no luck finding an opening in the field.

Ah, but Art, are you aware of the writers' strike now ongoing? Those writers are on strike, so what are Leno
and Letterman going to do without 'em? They're going to go insane trying to come up on their own with the
funny stuff they normally get from their writers. So there's yer chance, Art, go fer it! Yer all geared up fer
it as demonstrated in yer writings in the threads here on rraa. Don't miss this golden opportunity! We'll all
be listening as Leno and Letterman read yer jewels.

That nomenclature predates Kraus' book by quite some time.

The moment method is what NEC, MININEC, and most other antenna modeling programs use.

The description of the moment method in Kraus is excellent and easy to understand. It first appeared in the Second Edition.

I would guess that with the 8vsb modulation schema that was selected, they took the maximum cymbal rate that would fit into a 6Mhz channel, then selected a FEC rate that would sustain a reliability link budget. This dictated the bitrate of 19392659bps

http://www.broadcast.net/~sbe1/8vsb/8vsb.htm
http://en.wikipedia.org/wiki/8VSB#Bifurcation_of_digital_transmission_systems

Other modulation schemes exists that would fit into a 6Mhz channel such as 256QAM but theory dictates that the higher the bitrate, the more energy per bit that is required at the receive end to make a usable signal.

Gee Walter don'tyou consider yourself lucky to have got out of
hospital or what ever it was to get asylum.
Why don't YOU write a book and send it to Leno? Ofcourse like other
people they wont believe it
and look at it like a joke. Call it Reflections #4 1/2 that should get
a laugh
By the way stop that heavy drinking otherwise that asylum will be
beckoning you again and you will have to deal with those elephant
droppings again.

Cecil,
Velocity and acceleration are two different things
Velocity is the amount of movement and accelleration
is the rate of change of movement dependent on the
number of samples taken over a period of time
Joules are not necessarily accelerating.

The method of moments is a procedure that is more than a century old.
I was taught that in the study of materials and structures and I
am nearly a hundred years old. It is a mathematical term used in many
areas of science in solving for vector forces in areas of
equilibrium
or balance

http://www.maxim-ic.com/appnotes.cfm/appnote_number/750

has an interesting chart that shows the analog bandwidth requirements for various resolutions, including the 1080i and 720p HD formats, which are both shown as 26 MHz. This is misleading, however, since digitizing the signal results in data rates in the range of 1 Gb/s to 1.6 Gb/sec before compression, according to one source.

The compression algorithm can be "tweaked" to put the original program into almost any bandwidth. (The US Navy's "TV-Direct-to-Sailors" puts three TV programs into a 3.6 Mbps data stream. www.sia.org/2007DoDSatcomWorkshop/Wednesday/DoD/Navy.ppt I've seen it and it's OK.) Most compression algorithms are termed "lossy" because they lose some of the original data. The resulting deficiencies, called "artifacts" may be visible, depending on the amount of compression, the observer and the program material.

There are several modulation methods which will all put about the same data rate into a 6 MHz-wide channel.

hi

was trying to build a loop antenna i can use to hunt down some interference

seems it's pretty strong on 14.200mhz

i build a 2ft cross out of wood planning on feeding it w/ a short run of rg58u into pl259

questions:

how many turns of wire do i need? (spool of 26ga insul/solid)

do I need any capacitors or resistors etc aat the feedpoint if so what value??

thanks wasn't sure how to figure it out but i have to hunt down the interference as it's accross 1-30mhz and s9

thanks

The coupling to the steel roof pulls the traps out of resonance...
Call Hustler ... They have an updated tuning schedule for the 6BTV...
I don't have mine here at the office or I would offer it to you...
I found the 6BTV to be impossible to get tuned properly - even when
ground mounted per their instructions...
The answer - after I called them - was in tuning the traps along with
the length of the sliding sections... Their updated tune schedule
explains how to do it...

If after tuning the traps you have problems still, then I would
suggest an insulated mount with insulated-wire radials laid on the
roof... Put tape on the ends of the radials so they don't arc...

What is really happening is that the original venture capital
investors now understand that BPL is too flawed and that there will be
no big payday at the end for THEM, so they are busily recruiting 2nd,
3rd, 4th, etc., rounds of financing (i.e. new investors) so they can
recoup their initial venture capital and quietly leave the scene...
You are gonna see BPL trumpeted as the answer to everything in our
lives - manna from heaven, the new tomorrow - as they go through this
thrash to find the new money...

I had a 1/4WL 40m vertical with 8 elevated 1/4WL
radials sloping from 20 ft to 5 feet above ground.
At no time or distance did the vertical ever beat
the one-wavelength dipole in the general directions
of the dipole's maximum gain. I assumed it was because
the radials were not high enough and not horizontal.

> explain their error.

So far no response to this simple request. The
graphic of the non-reflected glass example is
at http://www.w5dxp.com/thinfilm.gif

We know that the reflections are 100% canceled
during steady-state.

The problem is: With the given data, calculate
the magnitude of the total reflection back toward
the source immediately after the first internal
reflection arrives back at the thin-film to air
surface at time t3 and is superposed with the
external reflection. The two superposed waves are
180 degrees apart.

The external reflection is 0.01 watts at a reference
angle of zero deg. This is the normal reflection
from the thin-film surface

The first internal reflection is 0.009801 watts
at 180 degrees. This is the first reflection from
the glass.

These two waves superpose at t3. The irradiance
equation, using P for power density, is:

Ptotal = P1 + P2 + 2*SQRT(P1*P2)cos(A)

where (A) is the angle between the two waves and
Ptotal is the total power density of the reflections
toward the source after the two waves are superposed.

Ptotal = 0.01 + 0.009801 + 2*SQRT(0.01*0.009801)(-1)

Ptotal = 0.019801 - 0.0198 = 0.000001 watt

There is 0.0198 watts of destructive interference
which, according to the conservation of energy
principle, must result in 0.0198 watts of
constructive interference in the opposite direction.

The magnitude of the reflection toward the source drops from 0.01 watt to 0.000001 watt at the arrival of the first internal reflection from the glass. That's a five magnitude reduction in the reflections at the time of the arrival of the first internal reflection. The reflections back toward the source are eventually completely eliminated during steady-state.

There was no vector math and no need to calculate the magnitudes and phases of the electric and magnetic fields - just a straight forward calculation to get the answer.

As long as the source remains in place, the steady-state cancellation of the reflections toward the source is permanent. It is difficult to analyze how that could happen unless the internal reflections interact with the external reflection resulting in wave cancellation.

Everyone is invited to prove the above calculation to be incorrect. Hint: if one actually performs a vector analysis, the magnitude of reflection result will be exactly the same as above.

The above method does not invalidate or replace a vector analysis. Unlike a vector analysis, it simply shows where the energy goes. Optical physicists knew this a century ago - most RF engineers have yet to learn it.

Which makes it fairly useless on 10m. 22 ft is just
about the maximum monopole height for good low
angle radiation on 10m. 17m is just about the
highest useful frequency for a 33 ft. monopole.

I had very good performance on 40m-10m feeding the
22 foot system with an SG-230.

The FCC minimums depend on the class of AM station.

1) 362 mV/m/kW at 1 km for Class As (equivalent to 225 mV/m/kW
at 1 mile for Class Is),

2) 282 mV/m/kW at 1 km for Class Bs (equivalent to 175 mV/m/kW
at 1 mile for Class IIs and Class IIIs), and

3) 241 mV/m/kW at 1 km for Class Cs (equivalent to 150 mV/m/kW
at 1 mile for Class IVs).

The groundwave field of a perfect 1/4-wave monopole over a perfect ground
plane is about 313 mV/m at 1 km for 1 kW of applied power.

This is almost (I had 4 radials) identical to what I once tried on 40. Also had an inverted V at about 45 feet at the same time. In making A/B comparisons with people 300 and 1000 miles away, those with verticals thought my vertical was better; those with dipoles thought the inverted V was better. Go figure. I no longer have the vertical.

What I am trying to understand is the current on each conductor of the 450 ohm line. Are the radials a high impedance on 20 meters with a 33 foot radiator? I can disconnect the radials and have an endfed zep and it works ok. Connecting the radials makes the antenna perform better and the tuning is different on the tuner in the shack.

Art, KB9MZ wrote:
"The "later" bit demands knowledge regarding the time constant of the inductor and the time at which all measurements were taken."

Time constant of a coil is L/R. Most coil designers work with Q which is 2 pi f L/R. Q works in most problems for a repetitive wave. Unless we are working with a one-off natural growth or decline cycle, why would we use the time constant without the angular frequency?

My experience with Mag mounts make me think that no matter what you use between the mag mount and the vehicle, there will be some scratching eventually, if you do what most people do....
That is, if you put the antenna there and leave it all of the time except perhaps to go through the car wash, it really won't make much of a difference, because all of the scratching I've encountered (small though it may be) seems unrelated to the mag mount itself, but the tiny bits of grit that is somehow washed or blown under the mount during typical driving conditions. When the vehicle was new, I was feeling younger, and more concerned about someone stealing the antenna, I would remove it and drop it into the back seat whenever I got somewhere, or parked in the garage. After a period of time, the garage filled up, I got lazy, and the antenna was pretty much always in the same spot. After a period of time, when removing the antenna, I noticed a small ring of dirt on the roof around the outside of the mount, but no damage to the paint. After a longer period of time without removing the antenna, I did notice some light scratching of the paint, but nothing that couldn't be fixed with some rubbing compound.

I would expect the felt to actually capture more grit over time, as the interface between the mount and vehicle is thicker (which, as you've noted, reduces the capacitance between the mount and vehicle, which changes the match). Besides changing the capacitance, the felt or other membrane also reduces the effective "grip" the antenna has, which can result in it inadvertently tipping at high wind speeds or when encountering a low hanging branch that wouldn't otherwise dislodge the antenna. This can result in more damage than the scratching you're probably concerned about at this point. Having performed a similar action (additional thickness between magnet and roof) I lost an antenna

and gathered an interesting shaped nick in the side of my truck as the antenna was tipped off of it's mount and swung by the cable to the side and whacked the body behind the door before I drove over the tip of the antenna, which had the predictable result of ripping the antenna off of it's cable (all at about 20 mph).

Anyway, if you consistently and periodicaly remove the antenna and make sure the location is clear underneath and wipe off the bottom of the mount before replacing it on the vehicle, I'd expect you won't have any paint damage at all for as long as you follow the procedure...

No, 25 foot radials laying on the ground are not a
high impedance on 20m. One side of the feedline sees
about 1200 ohms, the other side sees an impedance
probably much lower than 1200 ohms.

> I can disconnect the radials and have an endfed zep and it
> works ok.

With an unbalance of the currents. One side sees about
1200 ohms, the other side sees an open-circuit. An endfed
Zepp requires 1/4WL of feedline. Is your feedline an
odd multiple of 1/4WLs on 20m? Probably not unless you
designed it that way.

> Connecting the radials makes the antenna perform better and the
> tuning is different on the tuner in the shack.

Either way, you have common-mode currents on the feedline.
The radial configuration doesn't require 1/4WL of feedline
and may just be more efficient.

You ask to much of me. The "time " i was referring to was because of
the phenomina
of the tank circuit where one have to deal with overshoot as well as
the time constant of the circuit as a whole. The latter comes into
play
when one has to consider the equivalent of cavitation ala Bernolli
of the circuit as a whole .More to the point, one can measure the
current
at the entranceof a heat container which is sinosoidal, a varient and
then measure the current flow at the release of energy cycle when you
are dealing
with a varying DC flow of current which leads to oddities like having
higher measureable values than measured at the onset. Note that for
radiation one can increase one of the energy vessels while decreasing
the other such thatthe time constant varies greatly in terms of the
time varient such that the rate or gain of radiation is increased
(the other half of the slow wave phenomina) I say all this because the
subject
of the differences between didtributed loads and lumped loads is far
to complicated for me to fully understand.Similarly the time constant
of a resister
in a vacuum when one has to consider the equivalent to latent
heat in the transformation of energy
Sorry about that, this needs to be didscussed with a brown ale in hand

Presumably, the plastic looking things in the center
are insulators which makes the coils = loading coils.
But with CB antennas, one needs to be careful about
presumptions as some are designed for looks only.

Newsgroup: rec.radio.amateur.antenna
Date: 2007-11-08 18:54:05 UTC
From: scooterspal <tfg1@mindspring.com>
Message-ID: <hXIYi.43089$eY.2090@newssvr13.news.prodigy.net>
Source record: 34219

Hello to all and thanks for any help you can provide me.

Some time back I looked into installing a wifi antenna on the outside of my brick office building here in town. I would offer free wifi to the immediate area, shops, coffee houses, etc. and perhaps get some free advertising out of it.

When I investigated the installation of such an antenna I was stopped in my tracks because of the bonding (grounding) requirements. The need to install #6 copper wire from the antenna to the building ground on a direct external-to-the building path was something I was not prepared for.

Yesterday, the lottery agency had a defent size (bigger than home size) satellite dish installed on the roof of our building. There is a small store upstairs from me and this will replace the phone connection they had been using all these years.

As I look at the installation from the ground I can see what looks to be the coax wire and a greenish wire leading from the dish mast to the base of a vent pipe that has been on the roof. They lead in together at that point. The store is below. The roof is an A-frame and made of wood as is the entire building more or less.

Question: Is this to code? I do not believe it is since the ground wire, if that's what it is, leads inside the building somewhere and not externally to the main ground. If hit by lightning it would direct the energy into the building which is wrong.

Second, it leads away from the building bonding point, which is down on my ground level in the electrical room at one end of the building.

My hunch is it has been connected to a water pipe or electical conduit in the ceiling or wall.

I'd like to call the town electrical inspector but I want to make sure I am correct in this. The theory of bonding at least and the need for an external lead to building bonding point.

Recently, a building was hit by lightning in town and the damage went from the roof down three floors and was very extensive.

Can anyone advise me on this?

That gauge of wire will not provide and sort of lightening protection so it
can only be there for electrical safety. Are you sure that is requirement
really applies to the type of installation that you are undertaking?

No. I asked a question as to how that can be To which I later
theorised that
one can have "sliding" electrons as well as those that are pushed over
board.
The matter of "sliding" comes into play when you have a tipping force
to
overcome the tenacity of inertia in the face of a moving fulcrum.
But when you get down to the mathematical analysis it becomes obvious
that the summation of all vectors involved with radiation produces a
vector that does not align with the radiating axis which reinforces
the notion of "sliding electrons" or should I say sliding staic or
passive particles?
Still waiting for you to point to the error in Dr Davis's mathematics
such that the existing radiation theory can stay intact !.
I would point out that all computor programs on radiation show that
for maximising radiation of a particular polarity the summation
vector of all vectors involved with radiation is different to that
of the axis of the radiator which forces a shift in parallelism
to the earth's surface. This is an evolution of Gaussian law
which provides further insight to the laws of Maxwell who somehow
overlooked the connection between dynamic and static forces.
If the Gaussian mathematics is at fault then by logic all
computor programs must be suspect.
The tipping point is that computor programs ingnored a condition
that must be imposed if one is to view Maxwells collections
as a series of laws. It was this error which lead to viewing
the sino soidal shape of electrical current as constituting
the time varience required per Lorentz and others for the
production of radiation where as the time varience factor

is that obtained by the time constant of energy release of
distributed inductance and capacitance. The saving grace for
computor programing was its adherrence to the conservation
of energy theorem, energy in equals energy out which is
basically what the leanings of Gauss was.
Sowith elements that are resonant olone and in their entirety in a
array
produces a smaller array than that for a planar array such as a yagi.
On top of the reduction of element spacings it allows for helices
or the action of "slow waves" to reduce the htree dimensions of
freedom for any array down to a size of a half wave per side
noting at the same time one has only to feed one element and
yet gain the aperature presented by a stack of beams with
separate feed points
So I believe it behooves all to reexamine the mathematics
because if they are correct thben the rewards are humoungua.
Or play with your computor programs with non planar
radiating elements

That was an interesting read. I suggest you send your work to the IEEE to see what they make of it. If it all goes your way, you will have earned parity with all the "masters" you refer to so frequently.

That cannot be done. There are legitimate guru's on this net
and very near the top I would put Richard despite his arrogance,
jeering and painfull use of english.
But the fact is that those endowed with a knoweledge of radiation
have been bitten so many times by wishfull thinking of new antennas
that they have wandered firmly into the camp that all is known
and now dismiss all without the thought aplied that they are capable
of
I first started talk of radiation occurring in pulsatic form
on this forum many years ago when I first applied myself to the
science of antennas. This mere notion of mine started off this
adventure
where every adjective is being used to describe me.
However as somebody who came from the docklands of East Londonyou
are given the natural ability of sticking to your guns regardless
of what it does to your self esteem. I suspect I will go to my grave
before my work is taken seriously. And that is a shame. Not for me
but for the continuance of ham radio where we can again convince all
that ham radio is still at the cusp of new discoveries and have a
useful purpose in society. I am not asking for recognition of any sort
since as a former cockney I can handle adversity regardless how it is
formed
I can take it and I surely can give it out.(I remember Goring and his
bombers)

OK. Nobody will dispute that 33,000 foot pounds per minute can also be expressed as 745.2 joules per second, 745 million ergs per second, or 745.2 watts, so we have convertibility between mechanical and electrical power.

This thread is about antennas and one question was about small antennas. From Art`s post, I saw something about a slow wave. One might try slowing the wave to reduce its wavelength and the length of a wire antenna needed to effectively radiate RF energy.

Coiled wire slows a wave more than a straight wire does but it also usually has higher loss to heat. A dielectric coating such as polyethylene also slows a wave but adds cost, weight, and wind-loading.

Kraus has a nice section on "Electrically Small Antennas" which starts on page 709 of the 3rd edition of "Antennas". Everyone needs easy access to "Antennas".

Best regards, Richard Harrison, KB5WZI

Yes the extra length does increase natural resistance but at the same
time you can get symetry with re4spect to the timing of energy release
both sides of the pendulum If I remember rightly, I don't have the
book,
there is a chapter there on helecis antennas where there is great
emphasis
on the angle of the helixof the windings where some figures were
given
that were empically found, Well let me tell you that empirically
found
angles that are referred to there and every where else I consider to
that the summation of vectors involved be a reflection of the offset
angle to the antenna axis that following the Gauss aproach produces.
No it is not in any books. This angle has more ramifications that
people are not aware of especially in weather ansd satellite systems
that most assuredly would replace the transition to satellite
parabolic systems.
Let me share another aspectof my work with respect to Gauss.
Gauss did not work alone since he had an assistant.

Over time Gauss found that the incoming money was not enought
to continue to support him so eventually he gave up mathematics
with respect to the Universe and took a job at an abservatory
where he could view the same universe which he had phillosyfied upon
His assistant however piddled around doing the same old thing.
After gauss's death the assistant miraculasly came up with several
important
scientific discoveries which was out of place to those who knew him.
Not sure about the name but it might have been Ohm. So one may well
look back and wonder if the assistant was a scoundrel who came
to the surface after Gauss's death with ideas that he had reaped from
Gauss
but "neglected" to record. In such a light one wonders where the money
went
that Gauss could not find and why he had to give up his work!
One could speculate that if he wasn't forced to give up his work he
himself would applied a time varient to the statics law and stopped
for all time the common thinking that static electricity was just a
subset of
real electricity as it was known then.
Stanger than fiction or a silly detective story of mine I will never
know.
As Walter would say...That's the way it is. Write it up and send it to
CBS
because of the writers strike

Hi Art,

Considering that all electricity is produced by essentially mechanical methods e.g. the mechanical movement of a coil through a magnetic field (or vice versa) or by static friction or by chemical processes or by photoelectric processes, I would say that it is implicit that electricity and therefore all subsequent electrical phenomena are subject to mechanical laws.

It is also the case that certain electrical phenomena take place at scales where quantum physics rules the roost and therefore are incapable of being completely understood at our present level of scientific understanding.

Recently published research appears to indicate that there is a deeper level of theory that could be fully deterministic. A search at www.arxiv.org/abs/quant-ph/ should reveal a host of material on this subject.

So it looks like that was another prediction Einstein got right after all.

Ohh that's a loading coil alright, seen plenty of 'em at
cb-swap/meets/shows in the midwest. The shows used to be a lot more
open, now you have to know someone or be invited.

He should be warned, those BIG mobile amps draw a lot of amps and you'll
be into adding extra batteries in the trunk and alternators under the
hood! (think ambulance/swat-team/military vehicle industrial alternators.)

Also, those BIG base amps can cause you to drop a new box into yer
house/shack to supply the power--above 5KW just gets too crazy, IMHO ...
and don't even think about it unless you have a place out in the boonies.

Anything above the smallest base amp with the big tubes is kinda
crazy--IMHO.

You want to run more power than that, think about starting up a real
am/fm broadcast station!

Regards,
JS

Thank you for that
I went to thelink that you presented but I could not
make head or tail of what I was looking at!
Excuse my ignorance but is that link what you intended to send?
By the way I got an Email from somebody who remember at one time
there were thoughts of chucking Maxwell in some circles.
I can imagine their fraustrations
On a side note, Einstein was wrong many times
according to fellow scientists. Einstein was willing to
express his thoughts even tho it raised the spector of
possible rejection.
Where as, for my self, I have gone to a dance many times but
without taking the option of dancing just because
of the fear of rejection. I suspect that sort of thing
is more widespread than we all think which can then be
replaced by attitudes that are not welcomed by others.
Cheers
Art

Well, To *me*, I would want at LEAST #14 gauge. Of course, the large the
better. The rule of thumb, I believe is approximately one wire diameter per
turn. That would equate to the #14 wound at 8 turns per inch, and 12 @ 6
TPI and so on.

That link is to a site that publishes scientific research papers on a variety of subjects, in this case quantum physics. Few of the documents are expressed in terms that the layman could understand. I put the link in so that others can satisfy themselves that there is some documented background to my post. For lesser mortals a search through the New Scientist or Scientific American web pages will reveal some less technical documents, although they may not have the same level of academic provenance.

Like most scientists Einstein sounded out his ideas with other physicists and modified them in accordance with their suggestions or objections so as to arrive at the final polished product. His genius lay in the way in which

he developed his early theories while working substantially alone. He did have access to extensive libraries of information by virtue of his work in the patent office.

Just waiting to see if the East coast of the UK is going to disappear under the North Sea for a few days!

Hi, I'm not really sure what all of that means. I'm learning about
antennas, and I've been doing a lot of reading on the web until I can
get a copy of the ARRL Antenna book. I'm learning the terminology and
the other day read a thread about loading coils. I had no idea what that
was, so I went in search of an explanation. So, when I saw the radio
shop selling antennas with funny looking coils I wondered if that's what
a loading coil looked like. But I had expected a loading coil to be at
the bottom of the antenna, these looked like they might be in the middle
```

of the antenna. Does that even work?

BTW, I enjoy reading old threads from Roy and Cecil. A ton of great information there. I have learned alot, and have much more to learn. I want to try to make a 2 meter yagi (3 elements) this weekend and experiment a little. Maybe I can finally hit that repeater 30 miles away. ;-)

Well, that page deals with bootleg/illegal cb equipment. However, years
ago I bought a 1KW+ dave made amp which had been modified a bit and
covered 40-10m, it worked quite well, I drove it with a small homemade
xmitter I bought at a swap.

In addition to the material you are getting from the arrl
material--loads of amateurs have put together web pages dealing with
antennas/amps/equip. Most provide an email address and most are only
too glad to advise/help. And of course, you will find everyone here
interested in antennas and can share good advice, and you are quite
correct--Cecil, Roy and others have a LOT of good knowledge on amateur
antennas ...

Loading coils can be placed anywhere along the length of an antenna, for
varying effects on radiation pattern, matching requirements, etc.
EZNEC, Roys little program makes it a snap on graphing what to expect ...

Keep reading/studying, you'll get hooked and grab a license! :)

Regards,
JS

The antennas in the ad are center loaded antennas. Some of them are made very well, Im not sure of the ones in that particular ad. The ones of the design you ar looking at are often connected with some very unrealistic hype but for the most part they are a quality antennas at a reasonable price.

The ARRL Antenna Book is a very good choice.

The function of a loading coil, as you've probably learned, is to add inductive reactance at the feedpoint to cancel the capacitive reactance normally present when the antenna is short. This results in a purely resistive feedpoint impedance, which is the definition of resonance. There's nothing magic about resonance insofar as antenna radiation characteristics are concerned, but it often makes the antenna easier to match to the transmitter.

You can put the loading coil anywhere along the length of the antenna. As you move it higher, two things happen. The first is that the current it's carrying decreases. This decreases the coil loss, which is proportional to I^2. The other thing is that it has less effect on the feedpoint reactance, so you need more inductance in the coil. This increases the coil loss, which is approximately proportional to the length of wire making up the coil (all else being equal). The net result is that the overall coil loss is usually minimum at somewhere around the middle of the whip, which is why center loading is often used. Another benefit of center loading is that it might move the coil away from objects which it can couple to in a way as to increase its loss.

That being said, W8JI has pointed out that at least on the lower frequency bands, ground loss is so much greater than coil loss, that there's no point in going to much trouble to minimize coil loss unless it's outrageously high to begin with. This would have to be determined on a case-by-case basis.

Have fun!

Not a direct answer to your question, but practical guidance, I hope, since the interference is heard down to 1 MHz, in the AM broadcast band (approx. 0.520 - 1.710 MHz):

Most AM radios receive best when the antenna is aligned broadside to the signal arrival. They exhibit sharp signal dropouts or "nulls" when their built-in rod antennas are aligned with the signal arrival.

Try this: Tune an AM station and slowly rotate the radio. (It's probably better to use a battery powered radio.) You should hear two distinct nulls -- first in one position and again when the radio has been turned a half circle further. You may need to turn the radio on its back or side to hear the most obvious nulls as you rotate it.

Next, if you know where the transmitter is [http://www.fcc.gov/mb/audio/amq.html] you can relate its location to how the radio is positioned when you null that station.

So, you have a simple DF set. Now, tune *off* the station into a dead freq and try the same thing on the sound of the interference, trying for that null. Although you'll have two possible directions for the source, changing your location within the house should allow you to triangulate the source. You might need to go outside.

Caution: if it's getting on the power lines, it can drive you bats; One approach is to walk around with the radio and place it near plugged-in items -- even if you think they're off*. The buzz may get louder and softer as you move around, revealing the source.

A/C adapters and battery chargers are possible sources of such interference, as are dimmers and some computer monitors, although monitors tend to put out a "comb" of frequencies -- clear/noisy/clear/noisy as you tune the band. Put aquarium heaters, electric blankets, baby monitors and garage door

openers on the list of suspects. Many electrical or electronic devices have circuitry in them which could cause what you describe.

*My friend's VCR, even powered down, caused interference to his HF reception. Because the VCR has a clock/timer that runs all the time, his only solution was to unplug it when he wasn't using it.

Probably the bottom. The antennas are all shorter than a quarter wave and a
bottom loading coil would be likely.

What's with those power ratings? Thousands of times over legal CB and
unbelievable, too!

See http://www.vk1od.net/SmallUntunedSquareLoop/index.htm for some ideas. There are other articles on the site discussing similar antennas, their Antenna Factor, and measurements made with the antenna.

generally the higher up the antenna the loading coil is the more efficient
the antenna is... but there are tradeoffs in mechanical strength and wind
load.

548. Scanner Antenna Lenth Tuning to 1/4 Wavelength Question ?

Newsgroup: rec.radio.amateur.antenna
Date: 2007-11-09 17:24:09 UTC
From: Robert11 <rgsros@notme.com>
Message-ID: <BNGdneHu_d8oCqnanZ2dnUVZ_uWlnZ2d@comcast.com>
Source record: 34251

Hello,

Will be purchasing a scanner, and like most scanners these days, has a range of about 30 MHz to 1.2 GHz.

If I obtain a telescopic antenna for the unit, and wish to stick with just this antenna realizing it will always be sort of a compromise, the following question arises:

If I leave the antenna extended to its longest length, will this "automatically" provide me the best possible
broadband coverage on "all the frequencies (particularly at the low end), or is this long length negated by the fact that the antenna wouldn't be tuned to exactly 1/4 wavelength most of the time ?

I guess the question would relate mainly to what happens on the really low 30 - 50 MHz frequencies.

Must the antenna in that range "really" be tuned to exactly a 1/4 wavelenth to be effective, or you gain so much by
having a quite long length that exact tuning isn't all that necessary ?

Thanks,
Bob

Hi Bob,

The longest length will make your scanner deaf at the high
frequencies. This is because the long antenna (longer than 5/8ths of
a wave) wants to turn its focus along the line of the antenna itself,
instead of broadside. This trend gets progressively more focused
along the length as the length grows in relation to the wavelength.
(Or contrariwise, as the wavelength gets smaller for the same size
antenna.) As such, a one antenna for all bands (using just one wire)
is a poor choice.

>I guess the question would relate mainly to what happens on the really low
>30 - 50 MHz frequencies.

You stand to get good enough reception for antennas that are as short
as a tenth of a wavelength.

>Must the antenna in that range "really" be tuned to exactly a 1/4 wavelenth

No.

>to be effective, or you gain so much by
>having a quite long length that exact tuning isn't all that necessary ?

Use a variety of antennas, notably thick ones, to obtain a frequency
range of up to a couple of octaves. Overlap them to extend the range
further. If the term octave throws you, consider:
30-60
60-120
120-240
240-480
480-960
960-1920
Your scanner covers 5+ octaves. You probably need as few as 3
antennas, probably more.

Antonio Vernucci wrote:
"This is obviously a trick, but a well thought-out explanation could be of interest."

Radiated power is RF current squared x Radiation resistance. This makes the current into the antenna`s radiation resistance equal the square root of the (radiated power/ radiation resistance).

The radiation efficiency is the quotient of the (radiation resistance/radiation resistance+loss resistance). Thus, efficiency requires radiation resistance be high with regard to loss resistance. Loss resistance must equal zero for 100% efficiency.

Best regards, Richard Harrison, KB5WZI

Best scanner antenna I ever found was a discone mounted high, ~40 ft.
above ground.

I was able to pick up much traffic from even surrounding towns and
cities ... not perfect but provided more than was needed.

I've tried to model some OWA Yagis using MiniNEC or NEC-2 interfaces, like Eznec and 4NEC2 (a friend used also AO and YO), but the results are disappointing, especially regarding the impedance, which is one of the most important result for OWA.
Even entering real antennas, like the NW3Z 6 elements OWA yagis, the results are not correct...
For this and other reasons, I'm thinking about buying NEC-4 engine from LLNL and I would to know if this software is copy protected with some hardware dongle or software key or not.
I read the licensing documents and it seems that there is no copy protection supplied, is it true?

Really? When I built my OWA's (6 el 28 Mhz, also a 6 el 21 MHz) I used
EZNEC (NEC2). The SWR curve of the final antenna matched pretty well with
the modeling and I didn't need to adjust anything on the final antenna.
I used DX Engineering element brackets which insulate the element from
the boom.

Google for the Mike Holt Low Voltage Handbook. It covers all the NEC stuff for grounding antennas.

FWIW, the NEC bonding requirement is NOT for lightning protection (at least against a direct hit). It's more to insure that if something energized touches the antenna, that the fault current goes somewhere other than to someone touching a piece of equipment connected to the antenna. Think of it as similar to the "green wire" third prong ground.

And, for many installations, the coax shield can serve as the grounding conductor. For many cable TV/satellite dish installations, the coax will be routed (externally) to a grounding block, where a short continuous segment of aluminum or copper wire connects the coax shield to the building's grounding point.

Note that there are probably millions of improperly grounded dishes out there.

Guido
If you can't make them work then I would forget about computor
programs.
They obviously are not your cup of tea despite how many people use
them with success. You would be better off finding out what you are
doing wrong than sending money at the problem.

> How is 19.2Mb/sec calculated?
>
> Thanks!
>

The channel capacity (idealized) can be computed with Shannon's equation:

C = B * log2(1+ S/N)

From this we can see that you can get an arbitrary number of bits per
second through any bandwidth, if you have a high enough SNR and smart
enough channel coding. (viz, 56kbps telephone modems through a 3kHz
telephone wire channel)

there's a tradeoff, of course..

You can only radiate so much power (regulator and practical limits)
You can only point that power in so tight a beam (broadcast has to be
semi-omnidirectional, at least in a horizontal plane)
There's a practical limit to antenna size both at transmit and receive side.
You're ultimately limited by kTB noise at the receiver (most consumers
would balk at liquid helium cooled receivers)

So, what they did was pick a transmitter EIRP, a notional consumer
receive antenna gain and receiver noise figure, a typical radius to some
"service contour", and do the link budget..(with most of the numbers
chosen to match the existing analog services)

from that, they figure that they get enough SNR to support 19.2 Mbps
(with a substantial margin to allow for fading)

In this case, we can calculate backwards:
2^(19.2/6)-1 = S/N

S/N = 8.2 or about 9dB

The goal of the designer, then, is to figure out a coding and modulation
strategy that works well with the impairments typical of the path
(multipath probably is the most annoying one) and which allows

inexpensive receivers to be made, potentially at the expense of a more complex transmitter.

The 4 popular strategies are:
some form of n-ary PSK (8PSK)
QAM
COFDM
8VSB

all have pros and cons (some deal with multipath better, some are more efficient for transmitting with better peak/average ratio, some deal with doppler better).. For instance, on a satellite link from GEO, you don't have to agonize about doppler,and you want to run saturated amplifiers(for efficiency), so the PSK modulations are popular.

Once you know the bit rate, then it's a matter of coding/compressing the raw video (which for HD is several Gbps) to fit in the 19Mbps channel. Again, you want to push for simple decoders (which are going to be made and sold in millions) at the expense of complex encoders (which are going to be made and sold in dozens or hundreds).

Most of the compression standards allow for varying sophistication in the encoding process, all with the same decoder. For instance, you can do no frame-to-frame compression, in which case you'll have to lose a lot of detail in the frames to get it to fit (this is the cheap encoder). Or, you can use a fancier encoder that uses frame to frame compression (i.e. figure out the background once and send it once, then just send changes). Same decoder, but image quality is MUCH better.

Anyone who has "digital TV" from satellite or cable co has seen the difference in encoder quality. Things encoded at the broadcast network headend (where they've got more money) tend to look better than things encoded in the cable TV local headend (like local commercials).

Likewise, one can tradeoff speed of encoding.. you can do a good encoding job in much slower than real time cheaper than doing it in real time. So a pre-recorded program could be encoded/compressed to a high quality, without spending a huge amount of money.

Yes it is true. You could run it on as many of YOUR computers as you
care to.

No copy protection, just an organization with lots of expensive lawyers
with time to hunt you down. Not to mention that the software is export
controlled, so the crew of potential hunters includes the government,
which has very deep pockets indeed. When you get a copy, you sign a
license (not a click agreement.. a real piece of paper that you have to
send them) agreeing not to redistribute. If you happen to redistribute
to someone who shouldn't have the software, then you get to find out
(the hard way) all about the International Tariff on Arms Regulations
and similar export controls.

563. Is it possible to ask questions here?

Newsgroup: rec.radio.amateur.antenna
Date: 2007-11-09 21:23:56 UTC
From: Tom Horne <hornetd@veriqrmzon.net>
Message-ID: <Md4Zi.36$WN2.29@trnddc08>
Source record: 34266

Is it possible to ask questions here without triggering an arcane debate about competing views of theory. I'm about to find out. I asked earlier in another thread what measuring instruments I would need to have the use of in order to compare the effective radiated power of different antennas. As near as I can tell there was no answer.

I built a collinear J pole using copper tubing. I'd like to know if it is more or less effective at radiating whatever works to the stations I'd like to be able to talk to under conditions of emergency operation then say a collinear ground plane or any other omni directional antenna.

I would like to deploy the most effective practical antennas that field testing can devise and not have to wait until the next breakthrough in physics to be able to get my local governments Email out to my county's government, the state government and the responding relief forces.

My question, again, is what measuring instruments can be effectively applied to the comparison to provide results that will be born out by real world performance. I have to admit that I find the endless theoretical debate wearying. As long as it continuous then the newsgroup will be useless to newer licensees, like my self, who would like to get some "patient council to the beginner" from those of you who have been there and done that. Before I have to go there and do that would be soon enough.

In order to answer your question, one would need to know...
How accurately do you want to measure? If you want to know to tenths of a dB, that's a very different matter from, say, to the nearest 3 dB.

In most practical field antenna installations, local conditions and installation can result in field strength variations of +/- 3dB without needing to come up with absurd scenarios.

This is why most commercial emergency HF comm systems rely on fairly simple antennas which are fairly insensitive to surroundings (e.g. loaded folded dipoles, or wires with autotuners at the feedpoint, and so forth) and having enough RF power to accomodate the inevitable variations in performance.

Note that this is a VERY different scenario than the typical ham setup, where the ham wants to get the very best performance from limited power.

So, maybe your testing might be to work out the deployment details (what's easy to put up), and just do simple RF testing to make sure that your easy to deply scheme isn't "terrible" and is "good enough".

OTOH, if you're looking to do antenna shootouts with cases of beer riding on the results, a whole nother measurement methodology would be called for.

Now to practicalities...

Something like a Icom PCR1000 computer controlled HF receiver has a pretty accurate signal strength measuring feature, certainly, it's pretty good over small variations (10-20dB) in signal strength. You could put it at some distance (a mile away?) with a short whip (so the receiving antenna is nondirectional) and make your measurements. You'd put a fixed amount of power into the test antenna (i.e. set up your rig for, say, 10W out, and "put a brick on the key"..)

Actually, almost any receiver will do, if it has a reasonably stable way to check if the received signal is at the same level. You put a variable attenuator on the input, and just adjust it until the audio output voltage is the same, or the S-meter hits the same tick mark on the scale, etc. Since the receiver is always seeing the same level, things like nonlinear AGC or uncalibrated meters don't make any difference. It's all in the variable attenuator.

What's also important is making sure the transmitter power is really the same each time. You don't much care exactly what it is, just that it's the same. Almost any power meter can do this, as long as the system isn't too horribly mismatched. Remember, you're looking to hit the same mark, not have some absolute value. Big changes in mismatch mean that the quality of the forward and reverse balance in the meter will have an effect.

Easy way is to have
transmitter: power meter: tuner: feedline: antenna system.

Adjust the tuner for no reverse power on the meter, and there you go. (Of course, feedline and tuner losses are now part of your measurement)

People literally spend their entire lives doing this kind of thing professionally, so you need to take a step back and decide what level of measurement you need. For all you know, just doing some A/B comparisons when receiving WWV might be good enough.

All things being equal, a simple field strength meter will let you
compare different antennas. Those things needing to be equal are: all
the test antennas are all vertical or all are horizontal. The distance
from the radiating element to the pickup antenna on the FSM is always
the same, the power to the antenna is the same, perhaps others, as
well.

Any help?

Tom

Get together with some friends and have them drive out and assess your
signal under real life conditions. Make a day of it and all get together in
the evening for a social gathering and to compare notes. You really need to
know whether it works okay or not, not what the 'S' meter is reading.

A Field strength meter can be used to compare relative output of antennas.

"Most hams who strive for maximum radiation that is horizontally polarized place the radiator parallel to the earth`s surface."

Reflection from the ionosphere nakes unpredictable changes in polarization. Nevertheless, the angle of arrival equals the angle of reflection at the ionosphere. Experience shows best results on a transmission path happen when the antennas at both ends of the path are complimentary. See E.A. Laport, "Radio Antenna Engineering" page 215, "High Frequency Antennas".

Hi Tor,
problems begin when the first director is too close to the dipole...
How is the distance between DE and D1 in your antennas and, could you,
please, send me your .ez files, just to see your antennas.
Thanks and 73

There is no exect answer to the question. If you are only transmitting to one fixed station , the better types of antennas can be determined. If transmitting to several differant stations, there is usually no one antenna that will be the best.

Several times I and some of the local hams have been together and had mobile rigs with the same mounts and differant antennas. Swapping antennas from car to car, the results were differant depending on where the distance stations are. Sometimes the 1/4 wave would be beter and on the same mount a 5/8 or longer colinear would be beter on other stations. While we could not use it on the same mount, one ham had a 40 meter antenna on the bumper of his car and it had a beter receive signal on one repeater than the antennas cut for 2 meters we tried on the same car.

It is not so much as the effective radiatred power, but having both stations in the same lobe of the power. Antennas do not really give any gain to the signal, they just redirect the ammount you have to a differant direction. Just as a beam will have lots of gain, if it is not pointed at or near the desired station, they will not be heard.

Hi Art,
do you mean that NEC-2 works fine even with D1 very close to DE?
Other reasons for buying NEC-4 would be obtaining useful results with wires
near ground and connected wires with different diameters.

So, given that you want an omnidirectional antenna ("flat pancake"
radiation pattern), if I were in your shoes, I'd place a field
strength meter far enough away from the point at which I'm placing
each antenna I'll test that it's well into the far field, and then
install the antennas I want to test, feed them power from the
transmitter I'll be using, and see which gives the highest indicated
field strength. Note that you can take a liberal interpretation of
"field strength meter." It might well simply be the received signal
strength indication on a receiver at one of the remote sites you want
to communicate with. Note that this is getting really close to
testing exactly the condition you want to optimize. Why do otherwise
unless you have to? Why not try to optimize the communications on the
path that's giving you the most trouble now, and then verify that all
the others still work at least that well? You asked what instruments
can be effectively applied to provide results that will be borne out
by actual performance--to me, the best is a test of the performance

itself.

Implicit in this, to me, in the name of efficiency, is that you can try modelling some candidate antennas before building/buying physical versions to try out.

Also, you're not the first person to have this problem, and others have solved it various ways. You very well may be able to get recommendations from people who have. You may be able to borrow some of the common commercially available antennas to try, too.

Since the antenna itself is only one component of the overall communications channel, it seems to me that it would be good for you to step back and look too at other aspects of the channel. If you have limited resources to put into the project, it may well do more good to get a modest antenna up high at each site, than to put a "high gain" antenna in a bad location (e.g. too low).

I suppose there will be several people who will disagree with this and get into theoretical debates about why it can't be so, just as you say. But don't let that keep you from trying real antennas and finding out what really solves your particular problem.

I don't have any problems using AO which your friend has!
Have you looked at W4RNL pages on the antenna modelling?
He may very well have all the data you need on that antenna.

Guido,
Try looking for the "constant impedance antenna" which I put on the
net after I applied for a patent on it just before they came
out with that OWA antenna. W4RNL looked at OWA extensively and
found that it wasn't all that it was put up to be.
The "constant impedance antenna" is based on a closely coupled loop
to the driven element and certainly broadens the band width.
The OWA antenna is very similar to mine but as I remember they
changed the driver position compared to mine.
For those getting ready to flame, yes I did apply for a patent
well before the OWA came about and described it on this
newsgroup.

I have no problem with what you state when dealing with skip,
But not all antennas use the skip phenomina such as satellite
antennas,MRO antennas or those used for weather conditions
and wind shear nd ofcourse any helical design antenna
. What I was pointing out that if one was
looking for maximum gain of a specific structure then the
tipping angle comes into play. If you are looking for "max gain"
without reference to what type of structure of polarization
then yes, go ahead and do the standard axis parallel to the
ground method if you wish. I believe that most radio hams recognise
that a vertical polarised antenna is not the best type to use
when commnicating over ground with horizontally polarised antennas
and I suspect that even CBers are aware of that to.

Hi Tom

Direct field strength measurement at the "normal" coverage distances, calibrated and compared against a known/real world system is IMO the best choice. I was involved in a VHF paging project that used a laptop, GPS and measuring receiver for the job. The laptop had a A/D converter attached to the parallel port. This gave coverage results that were compared against a modeled prediction, but there is no reason you couldn't set it up to compare a "new" system to an existing/real one. One of the beauties of sampling over some time/distance is that small positional errors with nulls/peaks evident on VHF/UHF can be averaged or even studied as a distribution. The system I worked with you could even see Raleigh fading on, but for us it wasn't a useful output!

Biggest hurdle is the RX. You need some kind of Volts per dBm signal output. You could of course take an S meter output and calibrate it.

If you want a rough answer it may even be worthwhile attaching a laptop line input to an RX audio out and doing a visual/waterfall analysis of the level of (FM) quieting present with different antenna systems. You could of course also calibrate this system.

If you don't want to travel to the limits of the coverage area you can always do the tests at a lesser distance and then extrapolate with some RF coverage software.

Hope you find this helpful. Your comments on theoretical debates are noted, but the best you can do is to just not read them.

Well, in addition to a field strength meter, some low low power source
hooked onto to your antenna may help so you don't have to drive all over the
country side. I used an MFJ antenna Analyzer, some string, and a tape
measure, to 'map-out' on a graph locations of equal field strength.
Just have to watch out for your body affecting the signal pattern.

NEC is about wiring for human safety. However that ground wire is
also installed for lightning protection - from a direct strike. Those
who fail to first learn numbers will post only their feelings. That 6
AWG is sufficient to earth a direct lightning strike and still remain
intact.
> ... consider that a bare 18 AWG (1 mm diameter) copper wire, in

Above numbers are from the front page of a professional engineering
publication (Electrical Engineering Times) of 1 Oct 2007. That 6
AWG can be expected to conduct 200,000 amps which is ten times more
than current from the typically lightning bolt.

Meanwhile, every wire entering the building must connect to earth
ground before entering the building - also for lightning protection.
Even underground wires. Principles are summarized in a figure
entitled "The Need for Coordinated Protection":
http://www.erico.com/public/library/fep/technotes/tncr002.pdf

Unfortunately your WiFi antenna will act like a Ben Franklin
lightning rod. When (not if) lightning strikes it, then energy must
be dissipated somewhere. Either energy is dissipated harmlessly in
earth, or that energy is dissipated inside the house. How much energy
is dissipated in earth? Answer is determined by the quality of
earthing as the other end of that 6 AWG wire.

Often better is to mount the antenna so that lightning will strike a
higher mounting pole; to make a connection to earth that need not pass
through the antenna.

Better is to also route that WiFi wire to the building earth ground
before entering the building. Any transient that might try to enter
the transceiver via that antenna wire would first dump that energy
into earth via a ground block and short connection to the earthing
electrode. Dump energy into earth before wire enters the building.
Should you not do that, then better is to have that WiFi mounting pole
higher so that lightning will strike the pole; less likely to conduct

through antenna.

Mike
I already own the J pole I mentioned and an Isopole for two meters. I

expect to have a third two meter omni to cover APRS, Packet, and voice. I can see me throwing up each of these antennas in turn in a shopping center parking lot on a Saturday night when all the cars are gone and doing some measurements. I cannot see me rigging each in turn to the eve brackets on my house while my victims, I er mean buddies or at least they would be at first, cool their collective heals waiting for each successive test. Then there is the possibility that we may need to pre-install some sort of dual or mono band antenna at each of thirty plus fire stations and you can see why we might want to know which of the designs we can build or buy will put out the strongest signal. If I test at my home I will know which antenna works here but I'm unlikely to be called on to provide emergency communications from my home. I'd like to find out in as objective way as possible which antenna has the best chance in terms of power out to get the signal through in conditions that cannot be known in advance.

Art wrote:
"I believe that most hams recognise that a vertical polarised antenna is not the best type to use when communicating over ground with horizontally polarised antennas and I suspect that even CBers are aware of that too."

Crosspolarization creates an extreme loss if the ionosphere isn`t in the path constantly mixing the polarization.

For several years I worked in what was then the world`s largest shortwave broadcasting plant. All our antennas for many bands and target areas were horizontally polarized. I`ve visited many commercial shortwave plants and it`s the same story. Horizontal polarization predominates. Our antennas were designed for operation over 1-hop or 2-hop paths. They could be received with any piece of wire in any attitude but would likely work best with a rhombic or curtain that exactly matched the transmitting antenna but on the receiving end of the path. Those worked very well indeed on the program relay circuits.

C.B. is supposed to be a line-of-sight service. As mobile stations which may at any moment be located on any azimuth are involved, vertical antennas which don`t discriminate against any azimuth are likely the best choice for base and mobile stations which work together.

Please guys
Without going to war with each other over the answer and leaving me not
knowing who to believe, is an MFJ analyzer a good choice in the under
five hundred dollar range? Would using one of the one watt HTs do for a
signal source or is that still to high.

As you can see from some of the replies I gave to others I'm trying to
devise a way of practically comparing antennas available because in
emergency service communications support we have no way of knowing were
we will need to set up. Hence the desire to set up some sort of antenna
experiment that will allow us to compare the antennas against each other.

Just for the sake of my education is it likely to be true that the antenna that puts out the most effective radiated power will be a bad choice in a large percentage of possible sites?

Hi Tom

That's a very fair comment under the circumstances. That sounds like a pretty big project you are planning. Setting up an antenna farm in a big field or car park and plotting the antenna patterns with a field strength meter, or hooking up an Icom scanner to a PC and recording the results seem like the best suggestions so far.

Do remember that each site where you eventually install the antennas will have it's own characteristics. One design may not be suitable for everywhere. I personally have had very good results with a semi commercial 5/8 over 5/8 co-linear design with 6 x 24" horizontal radials at the base. The antenna is cut and tuned for the 2 metre band, but also works well on 70 Cm. Range fully quietening around 40 miles on only 5W on 2m across flat terrain with the base of the antenna 20 feet above ground. This is the most effective design I have come across for omni-directional working. The whole thing is built in a seamless fibre glass tube with the radials screwed into a ring bonded at the base of the antenna.

Good luck with the project

592. a little 4nec2 help?

Newsgroup: rec.radio.amateur.antenna
Date: 2007-11-10 04:25:35 UTC
From: s.g.hatch@gmail.com
Message-ID: <1194668735.353783.318990@o38g2000hse.googlegroups.com>
Source record: 34145

hello;

until now I have used 4nec2 to model cubical quad type antennas. Now, I have been asked to design an end-fire helical antenna with a groundplane. I've figured out how to model a ground plane using 'fast ground' and radials and stuff, but I'm having trouble with the excitation. I guess I don't really know the particulars of it. When I was designing cubical quads, I'd just slap it on the loop and be done with it; I assumed that nec was sort of making an open circuit in the loop and connecting a transmission line to it--that type of thing. How do I tell nec that I want one end of the conductors connected to the ground plane, and the other to the helix? Does it know somehow?

Any more tips on modeling helical antennas with ground planes in 4nec2?

Thanks alot for your help;
Sean.

Tom,

A one watt HT will do fine, but the signal will still be too strong close in to work with. You need to get the power down to perhaps one milliwatt or less to plot the antenna pattern in a field or car park. You can make up an attenuator to reduce the power from the HT. Just making up a patch lead between the HT and the antenna with a 50 ohm, 1 watt resistor shorting the core and outer will probably reduce the signal to something you can work with while still giving the transmitter a load to work into. (You can make up exactly 50 ohms using two 100 ohm, 1/2 watt resistors). Or make up a simple single transistor 'bug' transmitter from a handful of components. Plenty of designs available through Google No need to spend more than a couple of dollars. The 9v battery is likely to be the most expensive bit.

> Tom Horne, W3TDH

Tom,
I feel that the best results are achieved when measuring the field
strength/receiving effectiveness at a distance far enough away to
avoid near-field effects.
I have used a spectrum analyzer connected directly to the antenna to
make the measurements. Most units can read out directly in dB.
First, I had a friend that was about 2 miles away transmit and I
measured the amplitude of his signal at my home using my different
antennas. I was comparing a 1/4 wave ground plane to a homebrew 5
element beam.
We then reversed the setup, where he took the analyzer to his house
and measured the amplitudes of me transmitting using the different
antennas (same power output, of course)
Antenna gain difference and front/back ratio if it is a beam, are
easily measured. In my case, measurements were very close to
theoretical.

This is an expensive piece of test equipment, but someone in the area may have access to one.

On the other hand, if you are only looking for seat-of-pants measurements, find a few hams in the area with analog s-meters and have them give you relative signal strength readings for your different antennas. No cost, and the real test is whether you can communicate effectively. We often send out a rover in a car and do signal strength comparisons throughout the valley so we know where our signal needs improvement.
Good luck.

Mike's right - but if you don't have an MFJ 259 antenna analyzer yet, this would be a good excuse to go ahead and get one. Its just great when working with antennas.
You can get one for about half of your $500 budget.

596. Probably a stupid question...

Newsgroup: rec.radio.amateur.antenna

Is there a fairly quick answer to the question of what is involved with matching an RF amplifier to a whip antenna? I have built an active, tunable antenna to assist my shortwave receiver, and it works wonderfully on the 110' random-wire antenna up on the roof, but only picks up the strong stations with the whip. Those that it picks up come in great, but there are others that it is able to detect but not lock on to and make intelligable, IE BBC Africa, 7160 kHz around 0400/0500 UTC (and I am on the Gulf Coast of Texas).

Just wondering,

Thanks for any feedback or input.

Dave

A Palomar PFS-1 will do what you need done.
Unfortunately, they are out of production.

is the whip some sort of reduced size antenna?

The smaller an antenna is, the worse is the performance.

Tom

It has just occurred to me that if you can make or get hold of a switched
attenuator to stick in between the antenna and the input socket of your
remote receiver, you can make very accurate measurements indeed. I am
thinking of the type with 8 or 10 switches. The first switch gives 1dB of
attenuation, the next 2dB, 4dB, 8dB, and so on. So long as you have some
sort of signal strength meter you can monitor on the receiver, you just
switch in enough attenuation to give the same meter reading at each test

location and record how much attenuation you have switched in at that point. The more attenuation, the better the received signal. That will allow you to determine relative signal strength to within 1dB which is going to be good enough for your purposes. The attenuator can be used for all kinds of projects, so it might be worth taking the time to build one irrespective of what you end up using for a signal source. The usual Google search will turn up construction details, just resistors and switches in a screened box with some PCB offcuts or copper foil to provide internal screening between each section.

I agree with Hal, the MFJ kit is jolly good for the price. It does what it says on the box, just don't expect miracles.

> experiences with a vertical on 80 m here in central New Jersey:

While 4NEC2 is no doubt more accurate than MMANA-GAL barefoot, what I notice is that an arrray of verticals is usually better in its favored direction than any dipole below about a half wave.

Now to a more anecdotal discussion. Many years ago, I had an inverted vee like yours and a pair of Electrospace verticals phased with 16 radials each over Nova Scotia spruce forest type soil. The verticals clearly outplayed the inverted vee for extreme distances such as the middle east and VK or ZL. But the UK was more middle distance and mostly over water. One night Dale (now VE7GL) was testing, for a G2 ham, a sloper beam array with two steep sloper dipoles mounted either side if a delta reflector. With the back sloper also tuned as a reflector, these antennas lay down a very good low-angle pattern. Dale was around 20db over S9 on the vertical array and around S9 on the vee--according to the radio I was then using. Lou Varney (G5RV) broke in (using a G5RV) and mentioned that I was half an S-unit better with him on the vee. I noticed the same thing at my end. On the vee, Lou was almost equal to Dale. But on the vertical array, he went down about 3db while Dale came up about 20db. There was also a noticeable multi-phase quality to both signals on the vee that disappeared on Dale's signal on the vertical array.

Now, what I think was happening here was that my vee was picking up a lot of fairly high angle, multi-hop energy from both stations, while the verticals were favoring the large low-angle component of Dale's signal.

The moral of the story is that the antennas at both ends need to be optimum for one another.

Also, verticals do have significant ground losses in all but the most ideal locations. Raising the vertical(s) several feet above ground and supplying a resonant wire counterpoise will go a long way to reduce those losses. Furthermore, even a small active vertical or array can be a very effective receiving antenna, eliminating a whole lot of near distance QRM and QRN from your S/N ratio.

Of course back in that day, nothing beat W2HCW's yagi! :-)

Endorse that. Using the MFJ259B I have learned a lot about antennas and matching units (ATUs) ,not just antenna gain ,but also antenna bandwidth and (for HF freqs) dial settings for matching units.
Whereas the quality and uncertainty figures of the analyser might be frowned upon by 'professionals', it an excellent device for any radio amateur climbing the knowledge ladder.

==========
== 60 metres ,hence freq is 5 MHz ?
== Fixed frequency ?
== What is desired operating range ?
== What area is available to accommodate an antenna?

If for a limited range I would put up a single tubular (guyed) mast with a non-metal top end and fit an inverted V shape dipole with a suitable length of twin feeder and a current balun/choke near the transmitter ,assuming the transmitter needs to see a 50 Ohms resistive load.
The dipole would be 2 times 15 metres long with the twin feeder length 30 meters or a multiple thereof .

Alternatively an inverted V dipole ,length 2 times 30 metres with the twin feeder length 15 metres or an odd multiple thereof.

Your question is too broad , please specify purpose and operating freq/range of the transmitter.

Why not compare in the real world
Only the poster knows the conditions that he is likely to operate in
and it appears that it is in a very mixed environment.
In such a case I would compare antennas at home or some place
and move the frequency generator around to desired situations.
The generater can be a hand held or anything for that matter.
Now the real world does not care for "s" meters so one would
switch off the limitor in the radio and use a db counter at
the speaker.These results can be graphically recorded for direct
antenna comparison and for the record.
A sound DB counter can be obtained very cheaply
on E bay and the mechanics of comparison are in situations that
only the poster can determine. Lets face it , communication
is measured from what comes out of the speaker.
It is not rocket science!

Now spouting way too much theory to support my suggestions...

Antenna effectiveness is always affected grossly by physical location, height above ground and nearby obstructions. If you don't know where you need to setup in advance I assume you want to take some measurements and thus coverage predict when you do.

I'll stick to VHF/UHF systems only..

Antenna systems are relatively easy to predict performance of. Assuming you follow known gain figures, the only big problem (IMO) you will strike is excessive skying of radiation due to feedline etc radiation. This is commonly cured by "decoupling the line" through some means. - but I digress.

(Its strange you are looking at emergency comms, that is what the pager service was I worked on!)

I disagree that max ERP is undesirable. I assume of course you are talking omnidirectional antennas that tend to compress the vertical beamwidth. About the only time this isn't desirable is if you are in high mountainous country and need to either radiate into valleys or gain reflections from high angles.

I can see the problem you are trying to resolve now. I think however you need to take a multi tier approach and not just rely on a one time measurement at a test site. There are just too many variables to allow for when you move to a "real" location.

Do a number of basic field strength tests in variable topography at "normal" operating distances and maybe 3-4 locations with a calibrated measuring system. It doesn't have to be calibrated to an absolute figure but you need to be able to replicate the process from on test to the next. At some stage you will be able to create a table of -dBm vs whatever device you are using for measurement.

If you want to be pedantic play around with likely base antenna mounting height and method.

Make sure you do a distribution or at least minimally an average measurement over several wavelengths. When you come back and do the other antennas use the same measuring location. (A distribution will also give you an idea how "choppy" the signal will become for a mobile station)

Weather conditions may also influence results so try and do them at close to the same time/day

By variable topography I am talking a hill top, flat area and then a valley.

You'll now have some operating distance parameters that you can plug into a RF coverage program (like RadioMobile). You should be able to work backwards from the figures you got in the field to establish the actual antenna gain and radiation angle/lobe etc characteristics. You will even see the slight bump in the horiz plane pattern of a jpole.

The next step now in setting up for real world is to take the known antenna parameters and model actual locations that you need to cover for the emergency. IMO this will give you a much better idea of what your coverage will be without needing to do actual site measurements.

In other words you have now characterized your antennas and used a PC to establish what the coverage will be.

When you want to compare another antenna you'll need to go back to your test site for the greatest accuracy.

I assume you have done coverage modeling. The link below is not a good representation but will give you an idea of what the output looks like. In this case it is a 25W base to mobile 2m setup with a 5/8 on the car and 6dB collinear at the base. The base is off to the upper right of the image, the map is about 25 miles square and dBm is the scale on the top left. It is Tyler TX.

http://pages.suddenlink.net/vk2yqa/fig%20d%202M%20FM%20coverage%20from%20K5TDK%20base%20to%20mobile%20in%20Tyler.jpg

I hope you find this useful. I believe it far more accurate and useful for your application than comparing antenna ERP by itself.

Cheer Bob W5/VK2YQA

No. You need more antenna.

If you add amplification to a marginally performing antenna, you will
also amplify all the nearby interference: power line noise, dimmer
lights, electrical motors, poorly shielded TVs, etc. usw.

Sure, the desired signal(s) may come up in strength by adding more
amplification to a poor antenna, but everything you _don't_ want to hear
will be stronger, too.

Hi Tom,

There are one, two, three or four certainties about antenna
performance. There are dozens of factors that are way beyond your
control that degrade system performance. Emergencies rarely conform
to optimization; instead you need to think of flexibility.

>Hence the desire to set up some sort of antenna
>experiment that will allow us to compare the antennas against each other.

As has been offered by a multitude here, that is both very simple in
description and complex in accomplishment.

>Just for the sake of my education is it likely to be true that the
>antenna that puts out the most effective radiated power will be a bad
>choice in a large percentage of possible sites?

This question alone reveals a most curious idea. First, it presumes a
fact that has never, or should have never grown in your mind from all
the contributions here (or from external study):
Effective = Bad
is a non-starter.

Communications performance is measured by link budgets, not antennas
alone. The link budget is an accumulation of factors such as:
1. Applied Power;
2, Transmission line loss;
3. Antenna Gain (Effective Radiated Power);
4. Path Loss;
5. Receiver Sensitivity;
6. Multipath Sensitivity;
7. Noise in receive path.

This list could be made longer, but as long as it is, in an emergency
you really have no control over 4, 5, 6, and 7 (and you may be at some
risk even with 2 and 3). Your task as an emergency operator would be
to recognize and compensate for them as best as possible where it does
not jeopardize mission. Often, mission will negate any opportunity to
do anything about these last factors. This requires you to plan ahead

so that you recognize where these factors could occur and avoid them first, rather than being distracted with them after their discovery.

The difference between a J-Pole's performance measured on a range, and that of the standard ground plane is really negligible in comparison to putting either antenna into a Fresnel Zone where the multipath completely nulls the signal. They are BOTH dummy loads in that situation. So you carry a yagi to compensate and switch out the J-Pole or ground plane.

Unfortunately, you may not know where your contact is and you point the "optimal" antenna in the wrong direction. The best antenna does not supply the best result - but that is not a function of the antenna, but rather the operator (pilot error).

In a nutshell, the questions you are asking imply you are seeking assurance for managing risk, risk that is so variable that no assurance is possible. Links fail in the face of best efforts, that is why it is a hobby at our level of cash flow. $500 is not much of a premium payment for some emergencies.

The emergency repeater systems I've worked on have represented many 10s of thousands of (1970s) dollars as built up from surplused (MASTR II and similar) equipment. We spent more like thousands of (2007) dollars to get there.

Hi Dave,

You need more antenna...
... but not much more.

When I was in Africa with a Radio Shack $40 SW receiver, the whip was
a dummy load that let me hear the internal microprocessor clock that
was driving the digital display. I attached 20 feet of wire-wrap wire
to the whip, threw the wire end (weighted with a Rand) up onto the
reed roof of the lodge I was in and I got more signals than I could
handle with only about 4 meters of height. The bands from 2.3 MHz to
16 MHz played all day/night long.

For maximum power transfer from the antenna to the
receiving load, you need a matching network, i.e.
a low-loss antenna tuner. What is the dynamic gain
range of the receiving load device?

Media attention is one thing, but consumer attention is what really
counts. The following from the ARRL Letter of Nov 9, 2007:

"FCC Releases Broadband Report: The FCC has released their latest
report summarizing the state of broadband in the US as of December
2006. It shows that by December 2006, Internet-access BPL increased
slightly over December 2005, but also shows that it has been
decreasing slightly from a peak that occurred sometime around
mid-2006. According to the report, Broadband over Powerline ended up
with a deployment total of 0.006 percent of the total broadband lines
in the US, compared to 0.011 percent at the end of December 2005. You
can review the report on The FCC Web site
<http://hraunfoss.fcc.gov/edocs_public/attachmatch/DOC-277784A1.pdf>.

Looks like a drop of 45% for the mid-2006 to end-2006 period. In the
spirit of the season I'd say this turkey is just about done.

Well, BPL is ONLY meant to supply high speed to rural/remote sites,
homes, business, etc. As fiber goes into those areas (and cheaper
satellite, clearwire, etc.) some reduction will be noted in these--but,
keep your fingers crossed if you hate BPL.

In a perfect world we would all have megabyte speeds via
satellite--someday ...

We'll just have to find a way to make those satellites orbit closer to
the ground to eliminate that long round-trip delay.

Hi Tom

My approach to the problem of comparing antennas to each other would involve using satellite signals as the illuminator and build as many test antennas as you have interest in.

For 2 meter antennas, the 137 MHz from the NOAA satellites is probably close enough. That would require making some test antennas about 5% bigger than the 2meter antennas.

If you E-mail me I can show you some radiation patterns I have plotted from NOAA satellites. My plots of actual measured signal strength make me more and more confident that EZNEC is accurate.

Jerry

How's that going to eliminate the nearly half-second delay for me to get
a character echoed when I'm talking to a remote system via Telnet?

And that's not counting any other delays which might be introduced by
any other players in the connection.

If all you're doing is browsing the Web or watching videos, you'll
probably be happy.

Me, I'll take a terrestrial link any time. My 7Mb/sec DSL line is quite
satisfactory.

Bert Hyman wrote:

> What's the delay introduced by two 22,000 mile round trips?

Actually, it's around 26,000 miles, which makes the delay 186 / 52 or
about .297ms. This is far too high for VoIP or "video phones".

Here there are two competing "cable tv" services. They both get their
source material from satellites, however one delivers it via a terrestrial
cable and the other by retransmitting it to a satellite.

If you have both, you can flip back and forth on the same channel and
see the extra delay in the satellite network.

Geoff.

Hello, Roy, and all. Roy, I commend you for trying to provide correct insight into the misconceptions about electrical theory that is in the minds of some of our fellow hams. One can get a very practical and elementary theoretical knowledge through the ARRL's pubs. If one wants more than that I would advise some college-level courses (but be warned knowledge in applied mathematics such as vector calculus most likely will be required). For some of us our education, job and amateur radio hobby coincide.

Folks like you, Gerry Burke, Steve Best and David Pozar, to name a few, know antennas and antenna modeling. To the rest of those on r.r.a.a I would say that if Roy takes his time to respond you probably ought to listen. Sincerely,

With all the OSCAR satellites up there is no need to do go to the NOAA in the 137 mhz range. The two meter sats will do just fine.

Just because an antenna works well on a sat is no reason to assume it will work well on signals from the ground. I have not used one , but the old Ringo antenna sent most of its signal up at an angle. It would probably make a good sat antenna, but a poor antenna for ground work.

People in this thread are making way too much out of it. In most cases the longer/bigger the antenna is , the more gain it will have. Just put up the biggest one of good quality you can and don't worry about it. There will be enough differance in the lay of the land to make differant antennnas work beter in differant directions unless you are on a very flat land.

OK. I'll spell it out, usually I charge for teaching ...

You don't request one character, acknowledge receipt of it, then request
the next--GEESH!!!

Say you wish a 10 meg file. You send 1000 requests for CONSECUTIVE
10,000 byte packets, the satellite queues up what packet requests it
cannot send in parallel/immediately (depends on bandwidth, traffic,
processing power, etc.)

In the best case, the satellite would begin sending all compressed
packets at once (ALL 1000)--using
multi-threading/multi-processors/multi-channels, etc.

All happens quicker than poop through a goose! :-)

Of course, most elementary school students are already acquainted with
such methods of data transmission--well, at least 7th and 8th graders.

Next time, use google ...

Forgot one thing, which will be your next question.

After a 10,000 byte packet is xmitted, a error correct sum is computed upon the data in the packet and sent at the tail of the packet, this error correction sum is re-computed at the receivers end, if the two do NOT match, a resend of the packet in question in requested--this eliminates ALL possible errors ...

And, of course, great interference or poor/no signal can GREATLY slow data xmission ... which is a good reason to only implement redundant, robust models using the high state of technology at the time of implementation.

It would be nice if the war ended and the USA took one years war expenditures and implemented such a system for all American citizens.

Regards,
JS

Absolutely NOT, you see the news nightly, most often there is at least one news correspondent, somewhere, using satellite links to send in their report--they do it quite nicely--but yes, there is a bit of delay noticed--they/we live with it quite nicely--just like we do now with the transatlantic telephone cable(s)/satellite links.

Have you got a contract renewal coming up with Roy on his computor
programs?
This fawning over Roy is getting a bit heavy. Telling us on the
newsgroup
that should listen to Roy when we don't have a clue on your
background or even if you know what you are talking about is pushing
things a bit to hard(Judge not lest ye be judged)

I FOR ONE WOULD NEVER AGREE TO HIS STATEMENTS WITH RESPECT TO
NEWTON'S
LAWS NOT BEING APPLICABLE TO THE ELECTRICAL SCIENCE.

There is no doubt that Roy has a good memory for the books but I for
one
who likes to work from first principles is not happy with what is
in the books. Frankly, the books evolve around "every thing is known"
and everything in the books are correct. Thus anything that does
not conform with the books is trash. We are in a very sorry
state if our own Navy thrives on the same thinking aproach.
Nothing wrong in listening but we all have brains of our own
and it behooves to marry his words to those gained from first
principles.
Another thing where we differ.
Laws are laws and to add personal conditions invalidates those laws.
Roy's programs have a condition applied that is not proven!
ie it is an assumption that went with this type of programs

from it's inceptionn. Not to say his program is not as
good as people state but if you know what the answer should be
then mathematics can be used to validate them.
Ofcourse he believes I hate him which I don't, and thus the reason I
don't continually stroke his back like some do.
Nothing personal to either of you by the way, just observations.
Regards
Art KB9MZ.....XG

Hi Ralph

I missed being able to be clear in my "other" post. If there is a Beacon signal available from a POE satellite at 2meters there is an Excellent 2Meter source of signal with which a person can use to Very Accurately record the radiation pattern from horizon to horizon at all azimuth angles. That radiation pattern will be the pattern of the Ground antenna, not the satellite antenna. We have to assume the satellite radiates equal in all directions.

The strength of the received signal is recorded into some program like Excel as a function of time. The actual Az-El to the satellite is published, or can be computed. So, it becomes fairly easy to record the

actual (ground based) antenna's radiation pattern which includes all the environmental effects like trees and neighbors's houses.

No, and just for the record, the original work that became the Numerical Electromagnetics Code (NEC) was done by MBA Associates under contract to the U.S. Naval Research Laboratory in the `60s. The "Antenna Modeling Program" was turned over to LLNL who coordinated user-supplied enhancements to the original program.

> This fawning over Roy is getting a bit heavy.

It's not about fawning, it's about respect for someone who has earned it.

> Telling us on the

It was not my intent to imply that others on the ng aren't knowledgeable. I my response to some recent postings I previously stated electromagnetics is a mature science. The idea that somehow something has been missed by Maxwell, Heaviside or the many other contributing mathematicians and physicists over the decades to the theory, I find highly unlikely. The theory may be mature but you still need engineers to put it into practice.

Since it was brought up, I did my undergrad EE work at VPI&SU and master's EE work at The George Washington Univ (majoring in electrophysics). I was a signal officer in the US Army for 6 years and have worked at NRL since 1979 principally in the area of shipboard antenna and RF communications systems design. Is that enough? Over the years I have developed a high regard for "NEC Guru" Gerry Burke at LLNL and I know Gerry also has high regard for Roy. Sincerely, and 73s,

I'm sure you mean 297ms, or 0.297 sec.

A satellite doesn't have to be in geosynchronous orbit to carry telephone or other communication signals. The Iridium system uses satellites at about 500 km altitude, resulting in a round trip delay of about 3 ms when directly overhead. However, there's apparently still a noticeable speech delay, maybe due to the time taken to compress, decompress, and otherwise process the signal, and when a satellite is closer to the horizon. Iridium works basically like the cell phone system, except that the cells (in this case satellites), rather than the phones, move.

Oh I put my background on the web as well as my employment history
and only last week I added on your behalf that I am straight as
well as being married. When you state the truth you don't have to
worry about what you said yesteryear. I challenge you to do the same
that is a requirement for this newsgroupos utterings.
But it matters not what your background is only the veracity
of the statements.
I hold to my position that to view Newtons laws as unviable to
electrical science is totally in error.
I also add the following statement that most if not all antenna
programs
violated mathematical law by inserting a condition that can not be
proven and in fact is in error thus delegitamizing all the basics
for those programs.
Now some have said that the government
protects NEC 4. They have deep pockets so tell them of my statements
and let the law come after me. And you can give them confidence by
pointing to the errors in the math no less. Neither Roy, Woods or
anybody else
who has a finger in the pie with respect to NEC2 or NEC4 found reason
to
challenge the mathematics or my statements. As an aside, the
statements
have been made previously on this newsgroup and the silence from
those
considered expert was deafening
I made my case and look forward to seeing all the facts about you.
And yes Roy likes to know where you obtained your schooling
i.e place and subjects taken

Jerry you were clear to me. There are several things wrong trying to use
the sat to determine the patern of the antenna on the ground at other than
the specific pass. Low orbiting sats will start at a great distance as they
come over the horizon and get to with in a few hundred miles as they go over
head. The squnit angle of the sat antenna will change so the sat antenna is
not always pointing at the ground antenna. The apparent polarity will
change and that can make a big differance.

I have the KLM circular beam pair for 2 meters and 435 mhz on an az/el setup
and computer control. Also can switch from left to right circular and have
monitored the sats go over and sometimes have to switch left to right as
they pass for the best signal.

I have not tried it on a sat but for the Icoms (it might work on others)
there is a program that will record the s-meter and draw a plot on the
screen . I have done it looking at repeaters and it does seem to work ok
for drawing paterns.

I was an engineer o.k. Unlikely is like a horse race when a 50:1
horse comes in first. Unlikely infers it doesn't happen often
but it is accepted that it does. And I have shown that it has
happenned
again with Maxwell.; Unlikely yes but you have to acknoweledge that
it does happen and it is a sad day when it is prferable to putting
your head in a hole so you don't see it happened.
>

Yes that qualifies you as to being a worthy judge of the mathematics
presented by Dr Davis. Unlikely that he could be in error so which

way are you going or is it bury your head time but then it is
"unlikely"
You do youself little service if you deny the possibility of change.
Roy avoids change or any possibility of change and will fight to the
death preserving the truth implied by books.

> years I have developed a high regard for "NEC Guru" Gerry Burke at LLNL
> and I know Gerry also has high regard for Roy.

Yes, and both will defend the antenna programs to death even tho they
cannot point to the time varient that is implicit in Maxwells laws.
They know that one cannot add a condition or an assumption to a
given law in mathematics. And they added an assumption with respect
to the time varient. On top of that the assumption is in error.
Do you care? No because it is unlikely.

I presume you cannot either but content with having the herd
mentallity
The bottom line is you stroked Roy's back and then excluded everbody
else on this group of knoweing what they were talking about, this
in the face of the common errors enunciated by Roy.
I suspect you are biased possibly for contractual reasons
but then I recocognise that it is unlikely, but
Sincerely, and 73s,

Hi Ralph

Although I disagree with your premise about "great distance and a few
hundred miles", I must admit that I lack knowledge of the satellites other
than the few NOAA satellites. The NOAA satellites are about 4 time more
distant at the horizon than overhead. That results about 12 dB less signal

at the low elevation angle. The 12 dB is fairly easy to put back in the plot.
The guys at NASA/NOAA did an excellent job of tailoring the NOAA satellite pattern shape so it is close to equal over the entire pass. I'd have expected the "OSCAR" guys to have done the same and shaped their satellite antenna beams to be essentially equal level over the angle at which the Earth intercepts the satellite beam.
I'd like to know more about a 2Meter beacon satellite. Can you point me to a site where I can learn about 2Meter beacon satellites? I have a friend who will write me a program to plot signal strength as a function of angle on a polar plot. He made me one for the NOAA (137 MHz) satellites. I like modeling antennas at 2Meters and have an Icom PCR1000 that I'd like to get some use out of.

649. Helix angles

Newsgroup: rec.radio.amateur.antenna
Date: 2007-11-11 01:42:36 UTC
From: art <aunwin@insightbb.com>
Message-ID: <1194745356.350469.104100@d55g2000hsg.googlegroups.com>
Source record: 34102

When Klaus got involved with helix style antenna it was a great leap
forward
for antenna engineering. Klaus determined the best helix angle
empirically
and tho he made errors pertaining to gain, the empirical angles for a
helix
are still being used by even the most knoweledgable with respect
to antennas especially NASA. and the milititary
Why do the scientists still refer to these empirical figures instead
of using Maxwell's laws
to determine them? True, deviation from the exact angles does not have
serious
consequences in a lot of cases but why is science not willing to
update its procedures?
If Kraus was in error with respect to gains of long helices antennas
wouldn't it be advisable
to stay with Maxwellian figures?
The present thought is that the angle is somewhere between
10 and 15 degrees, and many dispute these figures. But we blindly
follow the books
on the understanding "all is known" and view in disdain the
"unlikely".

Hello Cecil,

Thank you for the interest, and the question. Last time I had the RF amplier on the scope and sig generator, it was giving me approximately 100 mV output with something that *looked* like a millivolt or two input (possibly at much as 5 mV but no more), at 5 and again at 10 MHz. Now, I am enough of an RF newbie that I *think* this is what you are asking, but if not then please enlighten me. I think I understand the need for a low-loss antenna tuner, which I am trying to improvise with a 25 ohm wire-wound pot acting as an autotransformer, ala The Miracle Whip (QST, July 2001 PP 32-35.) And it seems to be working to some extent, just not in the ideal way I need. I am able to pick up Radio Nederlands on 6145 kHz (I *think* that's the frequency) off of the whip, but not BBC Africa on 7160 kHz, even if the radio stops there and seems to realize that there is something going on, but just can't pull it out of the mud. I am able to pull in BBC Africa on 7160 kHz with the external 110' random-wire antenna, and that with a bare minumun of noise. The whip however, just gives me the noise. I am about to do some more experimenting with different WW pots to see if I can get anything better. If all of this sounds totally bat-shit, please forgive. It does seem to work at least half as good as I need however, and I am hoping to tease out the rest.

Please let me know if I am headed up the wrong creek with my answers. Hate to say it, but am honestly making this up as I go along (obviously).

Thanks again,

Dave

It has been stated on this antenna newsgroup that with
short antennas the current goes up the radiator and then turns back
and goes down. If this is so then it must be radiating all the time,
yes?
If a radiator is radiating all the time then the efficiency is the
same
as a full leght antenna. Yes?
This does not conform with reality Right?
So is it possible that the circuit (current)
returns along the path down the center of the radiator which is
bordered by decaying electrons which thus would prevent
radiation?
IF it was possible then radiation figures accepted by hams
would coincide with respect to short antennas. Yes?.
Then why do all the "experts" reject the notion of the circuit
continueing down the center of the radiator?
What exacly preventing such a circuit becoming a reality?
Why does current go up the radiator in the first place
knowing it has nowhere to go?
Just a silly question for the self perceived experts
Best regards and waiting in unabaited attention to responses
by the experts, as I can't find it in the books which tell all
that is known.
Your friend and eager listener

If the radiating circuit of a radiator goes up the radiator and then
down
or backtracking as the "experts" on this newsgroup states then
why is a short radiator not equaling the radiation or a full length
antenna, since the circuit is always on the surface of the radiator?
(stays on the surface until the frequency cycle completes)
Waiting in unabaited attention to be educated
(You know I want the reason why the circuit does not continue
down the center of the radiator eventually)

Hello Art, this is an easy one that any amateur could answer and which I would think is well below your level of the physics (so the reason for your question confuses me): If the antenna is perfectly resonant, then it, as a total charge distribution system or "circuit", has a time constant of zero. At any point along the length of the antenna, there are time constants that could apply, RC or R/L depending upon reactivity of the section in question. But you are asking about the distributed capacitance; what does that mean, let's say in terms of any point at a designated distance from feed point? Where do you want to calculate the time constant? Otherwise, once the antenna is resonant either by design or by the addition of reactive components (such as a coil in the center), as a whole it is a resonant circuit where reactive impedances cancel out and you are only left with resistance (ohmic + radiation resistance) and the time constant of the whole circuit must be zero.

You should know better (and I should know better for responding). :-}

The signal going down the centre would cancel the
signal going up the outside and nothing would be radiated except heat due to
the electrical impedence and resistance of the antenna conductor.

What keeps the two paths separated? A simple experiment with a length of
solid copper rod and a similar length of copper water pipe will demonstrate
that what you suggest doesn't in fact happen. Both will display similar
radiation characteristics and no sign of reverse current flows down the
centre of the rod or the inside bore of the tube. The only difference in
characteristics will be caused by a difference in the outer dimensions of
the copper rod and tube. At high enough frequencies, the tube will act as a
waveguide, but that's a completely different matter altogether.

Why does a light bulb glow? How do the photons know what direction to travel in?

If electrons are raised to a higher energy level (usually referred to as moved to occupy a higher orbital shell) by the input of energy, after a short period, they will return to their original energy state, emitting a photon to carry away the excess energy. The energy of the photon being directly in proportion to the energy input in the first place.

This has been verified repeatedly in published laboratory experiments. The photons are
emitted at around 300,000 Km/sec at right angles from the surface of the conductor. They don't need to 'know' which way to go or to be sucked out by some mystic force. Neither do we need degenerate or decaying electrons to direct the flow. An electron is an electron and nothing else. All electrons are inherently the same. When they form part of an atom, they can absorb or emit photons to balance the energy in the atom. The photon is not part of the electron, it is just the manifestation of temporarily stored, excess energy, being emitted to restore the atom back to its lowest energy state.

In a resonant circuit containing R, L, and C, there most definitely is a time constant. Related to Q, it describes the time taken for the circuit to respond to a transient. The higher the Q, the longer the time constant, and the longer it takes the circuit to come to equilibrium after a step or sinusoid is applied, and to decay after it's removed. Failure to understand this has resulted in some very poorly designed audio filters for CW, among other things.

The reactances in a resonant circuit cancel only at a single frequency. That means if you apply a sinusoidal signal at the resonant frequency for a very long time, and don't change anything about it (phase, amplitude, frequency, or waveshape), the resonant circuit will act like a resistor. But it won't under any other circumstances. As soon as you say "time constant", you're speaking of the response to a changing, not steady state sinusoidal, signal. And the response of the resonant circuit containing L and C to any change in the signal will be very different from the response of a resistor. And it will exhibit a time constant. (This can bee seen in the time domain equations for i(t) and v(t) which contain an exponential term multiplying the sinusoidal term. The time constant is in the exponent. See any text on electrical circuits for more detail.)

Mike I want to wait until some of the others present there thoughts
but one thing I have to comment on. The term is an electron is an
electron
and nothing else! I won't argue on the nomenclature of an electron
but must point out that an electrons has different properties!
You can have an electron that is bound to an atom via it's orbit
and that word bound cannot be underestimated. You can also have free
electrons
that attach themselves within to what we understand as matter.You can
also have
static particles where there are several states of decay right down
to a particle with chemical atributes but no electric atributes.
Now everybody brings photons into this picture that I will not comment
on
but as far as electrons one must state the electrons status before
debating
property changes that some suggest are foisted upon them.Lets wait to
see
what the others present though you didn't refer to the fact that if
the

circuit is always on the surface with respect to time then the
radiation
should be the same as a full size radiator. But that can wait.
Somebody may yet refer to a description from a book !
Best regards
Art

658. MI5 Persecution: Neil Fox (Nov/1998) (921)

Foxy's Showtime on Capital FM 25/11/98 7.35pm

Certainty level: 100%

This one, I can say with absolute certainty, is about me. It was recorded on my Sony Recording Walkman on the evening of Wednesday 25 November 1998. It doesn't mention me by name, so the objective observer might have trouble understanding why I'm so sure it's about me. I'm sure, because the harassment had restarted over the period when this piece was broadcast, and what Capital transmitted would have been in context with events at the time. (Sorry if that explanation is somewhat opaque, but I don't really want to embarrass myself by giving an explanation in detail, and an intelligent reader should be able to work it out for him/her self.)

This isn't the first time Capital have "got at" me; they were doing so right at the very beginning in summer 1990, when they said, "if he listens to Capital then he can't be all bad"; and Tarrant made remarks about me in his breakfast show in spring 1994, when he said, "you know this bloke? he says we're trying to kill him. We should be done for attempted manslaughter."

Unfortunately I didn't record those previous, much more conclusive instances of harassment by Capital DJs, and Capital Radio tells me they only keep recordings for three months. But lately I've been recording everything, and here is one product of that recording.

Neil Fox was introducing some petite Swedish songstress, sounded like Amelia, when he said something about her petite-ness ;

"she's a big big girl, actually she's really about tiny, she's this big, would you say what less than....."

then one of his studio staff shouted, "six inches"

then Fox laughed and said, "less than a meter tall, definitely"

What I think the "six inches" referred to should be obvious. I think it's sexual abuse directed at me.

Also there were a lot of words like "crazy", "mad" etc on this programme, which reinforced my belief that this was on purpose directed at myself.

I think Fox may be something of an unwilling participant in this abuse, he doesn't want to be an abuser but the persecutors are using his show and his staff to get at me. This is not the first time this sort of thing has happened from his show; and my guess is that it won't be the last

Agreed to. Especially the reference to equilibrium.
You are the first to acknoweledge that tenent
>
> The reactances in a resonant circuit cancel only at a single frequency.

Hold it right there.
Ohio state university placed that as a added assumtion to Maxwells
laws
and as you well know that it started to produce errors. This is the
reason that "moments" was brought into calculations because of the
way it averages or deals with errors. I suspect that an engineer
said get rid of that assumption if it doesn't work but like the saga
of the "O ring" with Nasa enegineers were ignored. This was at the
time I was wrestling with fortran and punched cards for computor
generated

BOM's that put me off of programming per say.You and others bandy
with
the words inductance and capacitance but you must know or should know
that both of these will not allow a sino soidal voltage or current
to pass intact thus one has to review where the time varience factor
comes from.especially when the used premise was found to be faulty.

But it won't under any other circumstances. As soon as you
> say "time constant", you're speaking of the response to a changing, not

> The time constant is in the exponent. See any text on electrical
> circuits for more detail.)

I cannot look at texts for an answer because
the texts use a prohibited method by adding a premise to a law.
You take the sinosoidal wave shape as the time varient despite
the errors it produces where as I do not. I do accept the laws
of Maxwell as stated as laws without the need to change things
because of outside pressures especially when it is accepted that
it produces errors by all concerned.

Where on earth did you get that from?
The circuit has two components that will not allow the sino soidal
circuit to pass intact
and radiation occurs because of a time varient.
So if the sino soidal current is changed to something else
then we have to look for an alternative for the time varience factor.
You have to start from a strong footing and you are not

You may neutralise the effect of components but you can't get rid of
the components themselves. They still have properties that come into
play with respect to the circuit

Best Regards

Hi Sean

If you are willing to let me learn along with you, I'd like to try modeling
your helix using EZNEC. I think I can model a helix over an infinite
ground plane using EZNEC.
I am interested in learning to use 4nec2but am a real poor learner,
especially when I dont bother to read the instructions.

> and goes down. If this is so then it must be radiating all the time,
> yes?

Yes, as long as the sinusoidal EMF is applied to the antenna. This is a forcing function. Let is assume a sinusoidal carrier wave is generated at the source.

> If a radiator is radiating all the time then the efficiency is the
> same
> as a full leght antenna. Yes?

No. The efficiency will be based on the ratio of radiation resistance to total resistance. Shorter antennas tend to require coils that increase ohmic resistive losses. Ground image plane losses can be huge on short mobile 80/160m mobile antennas. At lower frequencies, image plane losses can greatly exceed radiation resistance thus lower the efficiency greatly. Yet, the antenna is radiating 100% of the time, just not as efficiently.

> This does not conform with reality Right?

Yes, it does, per above. I guess with my elementary explanation, it is not helpful to go on the other questions since known science is contradicting your assumption (that some people, not necessarily you-yourself believe) antenna radiation efficiency is somehow related to the amount of time that current is flowing in the short antenna. I am not sure if you are intending to advocate this model or oppose it as I am not clear as to whose side you are on in this rather curiously controversial discussion of something that I thought was simpler. However, I am very open to expanding my horizons to new ideas since even today, antenna theory is to me a 'black art' (meaning that it is not fully mathematically understood by any one person that I am aware of also there are plenty of antenna companies making money based on empirical designs).

I am trying to conceptualize the design of your unique antenna model that you say is based on a gaussian extension to maxwell's equations. I have read your archives and I would like to try to understand your positions more specifically. You can throw the math at me. Can you point me to exactly which Gaussian extension formula I must apply to maxwell? Yes, I am familiar with the Gaussian area integrals of E*d(A) and how to solve them...I do have an EE degree. This area integral is actually a part of maxwell's equations and I do not know what extension you are referring to. I understand a Dr. Davis proved your work; can you point me to the calculations he did? That is

where I think I might learn a lot. BTW I have never used antenna modelling programs as I do not find the analyisis of repeated antenna segments particularly interesting. However, I may have to try it out to understand your stuff. Know of a good program I could download? It's called EZNEC or something like that? Thanks Art.

But Roy, I must first clear up that we are talking about apples and oranges. I was referencing a sinusoidal source of a frequency that is resonant to the circuit. You are talking about a transient can be treated as the sum of sinusoids which will not be resonant at the same curcuit. I was also referring to the antenna as a L-C-R circuit that does have time constants along its lengths (but I was asking 'where' along the length) but as a whole system the time contant of the antenna, when fed by a signal at resonant frequency is zero.

>
> The reactances in a resonant circuit cancel only at a single frequency.

My point exactly.

>But it won't under any other circumstances.

But Art didn't mention any other circumstances. Art seemed to be opposing any theory that thought charges were stored and released on antennas. I say this is exactly what happens on a resonant antenna. Transients will not efficiently transmit on the same antenna but I don't know how that relates to anything said.

As soon as you
> say "time constant", you're speaking of the response to a changing, not
> steady state sinusoidal, signal.

I agree that is what is usually the context. I wasn't sure what Art was getting at but I thought it was a very specific case.

I am attacking present day theory on the basis of what my reseach has
revealed over the past decade. I placed it in front of my peers
ie this newsgroup for examination. It was not examined in the normal
scientific way that I am accustomed to as an engineer.

If it was, it would quickly determine if the basis of my assault on
present
dogma were correct or in error. If you have existing progams you will
know
that sometimes it runs away for UNKNOWN reasons so YOU have to
determine
what is right and what is wrong. My research points to the inclusion
of
the sino soidal properties exist at every segment point and that is
known
by all parties concerned. It was shown to be correct at some segment
points but not all! But this asumption was kept in the absence of
known
alternatives. If you refuse to review mty work and its associated
mathematics then you are assuming that all is known even tho your
assumption
prove to be in error.I accepted that there were errors made and still
are
and have now found where the problem is. At the same time the solution
I
found resolves questions that scientists have puzzled about for over
100 years.
So if my peers will not review my work then I have to place parts that
are subject to contention which is going to be a verry long task and
perhaps irratable to many but I have no other options if all consider
everything is known. Now let me make just one point. I reffered to
the helix angle being determed empirically. Well I can show how
Maxwells
determines that angle using his laws. You also can determine using any
program that the angle is the summation of all vectors involed in
radiation.
The vector is not aligned with the radiator axis so with any program
move away
from planar forms to find that angle which produces maximum gain of
a desired polarity. How many of you used that method to avoid

relying
on a empirical method? Was it already known as with all the other
facts.
How many of you knew that an array that is non planar could exceed
the
attributes of a yagi? Or is that fallacious becuase all is known and
the books
cannot be wrong in any way when you have to acknoweledge that the
present
assumptions are known to create errors. I know, ignore the facts that
you know about and put your head in the sand and I you don't care
whether
the review by Dr Davis showed I was correct. To hell with the
mathematics
we know all is known because we have books that say so.
I am getting weary of all this but I cannot let it drop since I hold
to a
regimen that all engineers follow.
Go ahead Richard you can attack me now and not the subject as you
always do.
Art Unwin KB9MZ....xg

665. MI5 Persecution: Flying Eye (Mar/1999) (3095)

Newsgroup: rec.radio.amateur.antenna
Date: 2007-11-11 05:12:47 UTC
From: MI5Victim@mi5.gov.uk
Message-ID: <m07101109091423@4ax.com>

Jackie King from the Flying Eye 14/3/99

Certainty level: 40%

In early March 1999, Capital Radio alleged they had received some emails, one of which was forwarded to me. It contained the words, "you know this bloke, he says we're trying to kill him, we should be done for attempted manslaughter!" which Chris Tarrant had said in 1994.

Following these emails there was an explosion in abuse activity, both from Capital Radio, and from MI5 themselves. MI5 followed me around and hurled abuse at me. The following audio file contains what may be abuse from the radio station.

Jackie King from the Flying Eye made these remarks on Sunday (14/3/99) lunchtime 12.24pm; "gas main work being, er, HANDLED if you like (laughs, embarrassed) outside Madame Tussauds, Euston Road obviously feeling the backlash of that".

The key word is "handled", which she sounds embarrassed to be saying; to me it looks like an attempt at a sexual slander. Capital Radio aren't even pretending not to get at me any more. I asked Chris Tarrant several times about his remark from 1994, and he has consistently avoided answering.

Art, many people have acknowledged this. We were talking apples vs oranges.
It is a long strech to relate audio CW filters to antennas and their
distributed capacitance and inductance. Of course I agree when you involve
transients that have rise and fall times that are not related to antenna

resonance...I want out of this because I know we can make more sense.
>>
>> The reactances in a resonant circuit cancel only at a single frequency.
>> That means if you apply a sinusoidal signal at the resonant frequency

>> amplitude, frequency, or waveshape), the resonant circuit will act like
>> a resistor.

Yes. The resistor burns the energy, the reactors store and release it. Impedance is minimized, power transfer is maximized. That was my point to art, i.e. that a resonant antenna functions the same as a discreet resonant RLC circuit (except that part of the R is optimized for radiation resistance). Basic stuff, agree?

Huh? WHO at OSU did that??? Did they also modify Newton's Laws and Einstein's special relativity equations? I think you are saying that some teaching assistant had a pet theory that he was advocating to his freshman students while working on his Phd but it was likely later thrown out by his professor.

Do you mean those in the equatorial belt about 22,500 miles away?

They must be the ones which prompt satellite provides such as Wild Blue
to state that their service is not suitable for VOIP.

Art, I'm not sure if you read my entire post.

Where can I find a copy of your work? I have gone through the archives but no luck.

I actually *want* to review it (I do not "refuse" to reviw it as you posting says) and I can handle the math and will even learn EZNEC (or whatever you call it) if I need to model any of your concepts for a better understand. Also, a copy of the Davis post would be great to have.

Thanks,

Yep, those satellites which a signal takes ~0.12078436 second to reach.

Twice that for round trip. If you think a 0.24156872 second delay is
too much, I just don't know what to tell ya!

Yep, because they are beginning with the largest population of potential users to finance the whole operation and insure success.

Anywhere lacking lines which are insufficient to carry high speed are very valid markets. Although I live in a city of ~300,000 there is no DSL available at my residence--fortunately, I have cheap cable for my high speed needs.

For some strange reason, you just can't grasp the lack of importance
that amounts to.

But then, in the past, all your posts have implied a general lack of
resources on your part to grasp, digest and understand the new
technologies ... this is probably while you are still able to argue the
importance of CW with such fanatic voice.

Update: replaced the 25 ohm WW pot with a 1 ohm 4 watt WW potentiometer, with surprisingly good results. Am now able to pull in BBC Africa on 7160 kHz, although there is a somewhat faint high-pitch whine behind it. Still, it is definetly intelligable. At least 1000% better than it was. When attached to the external antenna, it is downright incredible. The only thing I have trouble picking up with the whip is WWV at 5 MHz (and 2.5 MHz is out of the question). With the external antenna however, these come through like gangbusters. The acid test will come at 1300 UTC when I try to pick up Voice of Korea. If I can pull that out of the noise, I will be ecstatic. That is what I have been working towards since I started this project. Oh, and it helps if all your wires are connected, and the one carrying the RF to the input of the first amplifier stage is not hanging loose, near it's intended connectionpoint, due to a broken solder joint. Found that while installing the 1 ohm pot and had to go back and see how the 25 ohm pot performed once the wire was reconnected. Better, but still not ideal by any means. Then installed the 1 ohm pot, and got surprised. If you want to see the schematic, I can post it to alt.binaries.schematics.electronic.

Hoping to hear from you again on how to improve reception further.

Thanks,

Dave

677. MI5 Persecution: Johnny Boy (21/Aug/1998) (5269)

Newsgroup: rec.radio.amateur.antenna
Date: 2007-11-11 06:45:33 UTC
From: MI5Victim@mi5.gov.uk
Message-ID: <m07101110420218@4ax.com>
Source record: 34131
Cross-posted to: rec.outdoors.fishing.fly.tying,rec.radio.amateur.antenna,soc.support.depression.treatment,alt.tv.shaggable.babes,dk.snak.mudderkastning

Virgin Radio-Johnny Boy (21/August/1998)

Certainty level: 60%

On Saturday 15 August 1998 I attended a gathering of contributors to newsgroup uk.misc at London's Victoria railway station. Also present was Simon G, who had previously given this description of what he would be wearing;

At 06:36 AM 13/8/98 GMT, Simon wrote:
>further clarification to aid recognition, i'll be wearing
>a t shirt, a brown suede waistcoat, a brown suede miniskirt,
>& a pair of patchwork leggings (& may have a widebrimmed straw
>hat, too).

It is my belief that my persecutors, who monitor my home telephone line (and consequently read all modem communications including email), were aware of this meeting, and may even have observed the "meat" taking place.

Following the "meat" it seemed to me that one or two attempts were made by my persecutors to portray me as "gay", on the basis of Simon's suede miniskirt, which in their inventiveness my persecutors attributed to me, not Simon. (Just for the record, Simon is hetero, and has agreed to the above email extract being published.) The following item from Johnny Boy's Wheels of Steel (between 7pm-11pm, Friday 21/8/98) is one such attempt.

(conversation) (J=Johnny-Boy, H=Hipster)

J: Texas of course part of V98 this weekend enjoy it if you're going. Keep your eyes out on Sunday in Chelmsford for Hipster, because he's going to be there. What are you going to be wearing?

H: I'll be wearing my, er, my suede shorts.
(sycophantic laughter)

J: and believe me he ain't joking, he ain't joking. OK coming next at Virgin on the Wheels of Steel...

Why do I think Hipster's "suede shorts" refers to Simon's mini-skirt? Because "suede" in both cases (obvious!); because "suede shorts" indicates "gay" which they were trying to pin on me; because "shorts" = something short, such as a "mini"-skirt; and because the two DJs both laughed as soon as Hipster said "suede shorts", they knew what the joke was, they knew that they were meant (and probably paid) to find it funny.

678. MI5 Persecution: Johnny Boy (19/June/1999) (7443)

Newsgroup: rec.radio.amateur.antenna
Date: 2007-11-11 07:45:42 UTC
From: MI5Victim@mi5.gov.uk
Message-ID: <m07101111421193@4ax.com>
Source record: 34133
Cross-posted to: rec.outdoors.fishing.fly.tying,rec.radio.amateur.antenna,soc.support.depression.treatment,alt.tv.shaggable.babes,dk.snak.mudderkastning

Virgin Radio-Johnny Boy (19/June/1999)

Certainty level: 30%

I'm not quite sure about this one, so I've given it a one in three chance of being about me. First the background.... from mid-March 1999 for some three or four months, every weekend, I bombarded Westminster MPs with faxes about the terrible, all-encompassing MI5 Persecution. (Jesting aside, it really is terrible and all-encompassing, in the UK anyway.) Of course each week some MPs replied; but in June 1999, after I'd been at it some three months, I started getting "covert" feedback from Virgin Radio.

The first feedback I got was from Danny Baker, on Sunday 13th June. That weekend I was sending an article which contained biting criticism of the police inaction in this case. Danny Baker on his Virgin radio show started an angry rant that "he knows it's rubbish", ie. he was rubbishing what I'd said in that weekend's faxed article. Unfortunately I wasn't recording this programme.

The next possible Virgin-Radio feedback was a week later on 19th June 1999. This is contained in the audio file above, in which Johnny Boy on his "Wheels of Steel" programme says;

"and if you would like to put a triple play together, ahhh.... because quite frankly Hipster and me are running out of ideas...."

He goes on to counter Hipster's "how dare you" with a protestation that he is "only joking".

What I reckon is that my article faxed to MPs that weekend was forwarded by one of the recipients to Virgin Radio. My article had included the words;

"I am beginning to run out of both new topics and energy to write these articles."

So what I reckon is that Johnny Boy read the article.... and rephrased the above line "run out of ... new topics" to "running out of ideas". I recognise that this is a pretty tenuous inference to make.... but do listen to the audio file, from the "ahhh...." pause in JB's speech you can guess he is about to say something "risky" and at someone's expense. Anyway, I listen to the Wheels of Steel regularly and will continue to do so, recording it as I always do - so any future funny remarks will get immortalised on these pages!

Brighton Day Trip - 24/Sept/1998

Certainty level: 5%

On a day trip to Brighton, carrying a minidisc recorder, I managed to collect several indistinct instances of what I think were people swearing at me. Between the 0.5 and 1.5 second marks of the above recording is something that sounds like "nutter". I recorded at least three other much more obscene sexual words on the same day.

I don't honestly think the "nutter" recorded here is part of the conspiracy against me. I've been called similar things elsewhere, where it's been blindingly clear that the insult does form part of the conspiracy - but not in this case. This illustrates quite a worrying point - as a result of the many years of abuse "in public", I now sometimes simply don't know whether somebody is insulting me because they think I look like a dweeb, or whether the conspiracy is in action. Sometimes, due to background noise and people talking quietly relative to ambient noise, I can't be sure of what's being said, even after listening to it again on my minidisc. Or put another way, I now have a mild form of what I recognise to be occasional auditory delusions - but these are fuelled by the many years of actual verbal abuse.

POSK Cafe - 2/Feb/1998

Here are two independent segments, both of which occurred in London on the same day, the first at a Polish cafe, the second on the Tube.

Certainty level: 100%

POSK is the Polish Social-Cultural Centre in Hammersmith, London. It has quite a nice cafe which does pierogi, golabki etc. I went there with my mother early in 1998. Seated at the window table were three Polish men talking amongst themselves. One of them let rip with a sexual obscenity which was clearly directed at me (it's the same one that's been heard again and again since about November 1995), and which was recorded on my minidisc walkman. I have not included it in the above excerpt, which shows the reaction of another of the trio to the first man's swearing - namely, "jestes swinia jednak" which in English is "nevertheless you're a swine".

Certainty level: 20%

Somewhere on the London Underground. "Psycho" (I think - a little unclear).

You've lost me. What is the meaning of a "time constant" in steady
state? What effect does it have? With a single frequency of constant
amplitude, how could you tell whether a circuit, resonant or not, has a
"time constant"? How could you measure it?

Roy Lewallen, W7EL

682. MI5 Persecution: Leicester Square 9/2/98 (13965)

Newsgroup: rec.radio.amateur.antenna
Date: 2007-11-11 10:49:20 UTC
From: MI5Victim@mi5.gov.uk
Message-ID: <m07101114454808@4ax.com>
Source record: 34049
Cross-posted to: rec.outdoors.fishing.fly.tying,rec.radio.amateur.antenna,soc.support.depression.treatment,alt.tv.shaggable.babes, dk.snak.mudderkastning

Leicester Square - 9/Feb/1998

In February 1998 I spent some time in Leicester Square, in the West End of London. This is a very busy area of London, and one which can be relied on to produce "contacts". Capital Radio's offices and their cafe are located here, the Trocadero is nearby, and the place is full of cinemas and entertainment venues.

Certainty level: 100%

A young girl is heard to say, "Alright I'm going to talk to myself" to her friends, followed by all of them laughing together, as I passed by.

Believe me, I do not look mad in real life, these young people would not have directed their comments and laughter at me unless they had already been told by others that I was ill. I am absolutely certain that their behaviour was directed at me, and this audio file is particularly clear.

Certainty level: 60%

This one was recorded in a cafe in Green Park. Two women are talking to each other, one of them says to the other, "something wrong with him", with an emphasis on the "wrong".

The words "something wrong with him" have been repeated at me dozens of times, at my former workplace in Canada, in England, etc. The words are quite deliberately chosen to have two meanings; they obviously imply that I am ill, without forcing the abusers to demean themselves by using more pejorative terms, although they have shown that they have no compunction in that area; and secondly, the words "wrong ... him" make me at fault, and place the guilt for the abusers' wrongdoing on my shoulders.

Certainty level: 30%

Recorded on a Victoria line tube train leaving Green Park station.
If you listen carefully you can pick up the word "hunchback". The speaker had emitted a swear word immediately before this excerpt; both the swear word, and the "hunchback", were (I believe) directed at me.

> yes? If a radiator is radiating all the time then the efficiency is the
> same as a full leght antenna. Yes? This does not conform with
> reality Right?

Wrong, as regards your "reality." Using the classic definition of efficiency, an antenna of ANY length (including a point source) will radiate nearly 100% of the power it accepts from the r-f source driving it.

The radiation patterns of those antennas will vary. Some will radiate more relative field in some directions and less in some directions than others will. But, disregarding dielectric and conductor I^2R losses, ALL antennas radiate ALL of the power they accept from their driving source (ie, their efficiencies are equal).

> So is it possible that the circuit (current) returns along
> the path down the center of the radiator...

No, it's not possible. No matter the direction of flow along a solid conductor, alternating current tends to travel on/near its outer surface. This is due to the greater number of enclosed lines of magnetic flux generated by current flowing at/near its center, which increases the inductive reactance of the conductor in those areas. The result is a redistribution of the current to the parts of the conductor cross-section having the least reactance, ie, on and near its outer surface. Read Terman's RADIO ENGINEERS' HANDBOOK, 1943 edition, pp 30-31 for more on this (or many other sources).

> IF it was possible then radiation figures accepted by hams
> would coincide with respect to short antennas. Yes?.
> Then why do all the "experts" reject the notion of the circuit
> continueing down the center of the radiator?

Because it doesn't do that.

Is this a prelude to your normal comment when you walk away?
This I don't understand is a cop out but I will answer you anyway.
The meaning of time constant. You are aware that the addition of
other things that was not part of Maxwells laws such as the assumption
of
a sino soidal current at every point taken for the calculation
produced errors.
As one who sells the NEC work you must know that.
If it produces errors then the assumption is in correct yet Maxwells
laws are based
on radiation from the time varient phenomina. Thus it behooves all to

impose the correct or alternative time varient.An alternative time
varient is exposed
when one adds a time varient to the law of statics which is shown to
equal
or be the same as Maxwells laws(see the math in the archives.
Using Gauss's method of analysis which is based around flux and an
arbitary field
shows radiation is formed in pulses during times that equilibrium is
broken
and the arbitary borders fracture momentarily. The only way therefore
is the
circuit is one of a tank circuit. The tank circuit mby use of the
radiators constituent
capacitance and inductance revolves the time constant associated with
a sino soidal
property and with the syncroness of energy release according to the
time constant
of the energy storage imposes a time varient. Now the math is there so
next we
allow a computor program with unknown viability to compare with
Gauss's law
extension that I imposed.
What does this show?
Using the optimiser version it allways migrates to a non planar form
and not the planar form
which scientists have mimiced from the yagi. Doing this it supplies
the angle for a helix
that is mathematically supplied by Maxwell where prior to this it was
emperically found.
One can overcheck this by placing a non planar form into any passive
antenna program
and it verifies the results of a Gaussian apoproach. Since using the
time varience
associated with a sino soidal produces errors and the time constant
of heat storage release
does not produce errors to Maxwells laws it behooves all to review the
significance of what I did
which is to add a time variable to the same proven situation that
Gauss applied for statics.
a proven method which does not violate Maxwells laws.
. For your part you can examine the mathematical aproach taken for
error since it is at the core
of what I present. If you wish to modify it so it conforms with the
books I will give
it a fair hearing without defaulting to the "all is known" syndrome.I
cannot agree to adding
any assumptions to Maxwells laws since that delegitamises any law as
we know it.
Science demands impartial examination without imposing pre supposed
conditions or the

involvement of personal feelings since it is continually found that
what is unlikely to happen
does actually happen!
Questions to ask yourself.
How is it that Maxwell defined the angle for a helix that matches
thatfound by Kraus empirically
by not using the time varient assumptions that we presently used
associated with the sino soidal
wave?

Dave,
In a nut-shell, a larger antenna will tend to be more 'receptive'
at lower frequencies. Then you can think about matching the
impedances of the antenna system and receiver.
Larger antennas have the 'problem' of being 'larger', as in where
do you put the thing? Reducing the size of an antenna can be more
practical mechanically, but tends to be less practical electrically
(noise, less 'receptive', etc, etc.). Your 'best' bet would be to
find a reasonable compromise between the two kinds of 'practical'
thingys (mechanical/electrical). Usually easier if you can make it
bigger, sort of.

>
> Can anyone tell me where to get one
>
> A web ddresss? ?

That's sort of a 'broad' question. Depends a lot on where the
antenna is to be situated and the state of your bank account versus
your building abilities.
An antenna's environment determines much of it's electrical
characteristics, so that can be an important part of the 'selecting'
process. An antenna's mechanical characteristics also are part of
that 'selecting' process. There are gobs of antenna 'styles'/types so
those mechanical 'problems' can usually be sorted out easily, sort of.
Can't give you a particular address for that antenna, but would
suggest doing lots of 'shopping' before buying. Making one to fill
your need isn't unreasonable at all and can certainly be cheaper
(important consideration if you're as 'cheap' as I am!).
Good luck.

Jerry you can find information on the ham sats at www.amsat.org.

I guess the great distances I was thinking about was from about 200 miles to
around 1000 or so. As you said that is getting close to 10 to 12 db
differant. In one way that is not really that much differance in signal,
but the types of antennas we have been talking about would have from 0 db to
about 6 db of gain. Most would have just one or two db worth of differance
in the best direction.

If the cities have cable and DSL broadband, and the BPL folks have often stated that their market is the underserved rural areas, it doesn't really make sense for them to concentrate on cities and suburbs.

> Anywhere lacking lines which are insufficient to carry high speed are

So you're in a city and you have broadband. You aren't a guy who needs BPL. I live 3.5 miles from a small village of 1200. I have DSL. I'm not a guy who needs BPL.

A lot of this 'discussion' depends on how you define 'efficiency'.
A 'point source' can be very efficient, in it's self. It can also be very inefficient when compared to another type 'source'.
It's true that any antenna can radiate all of the signal getting to it. The 'catch' is just how much 'signal' is getting to it and how/where is it being radiated. If it's going to where you want it, and if a usable amount of 'signal' gets there, then it's efficient for that particular situation. If not... then it isn't very efficient, is it?
- 'Doc

(With the 'proper' mind-set, you can apply the above to anything, not just antennas.)

The fact is, "John", the same lag exists no matter how much data
compaction takes place.

I understand BPL just fine, "John". I also understand the lag time
which exists when utilizing a geosynchronous satellite. The sats are
not a "new technology."

> ...this is probably while you are still able to argue the
> importance of CW with such fanatic voice.

I submit that you are unable to hear my voice. I didn't bring up the
topic of CW. I've used CW through AO-10 and other birds. At apogee,
there was a very noticeable lag. At perigee, the lag was less.

The fact remains that one of the providers of satellite internet service
sees a need to place a disclaimer on its web site that its service won't
support VoIP. No amount of tap dancing changes that fact.

Now thats funny.

Slow down Mr. Smith, you are guilty of the thing you are accusing Dave of.

What he is saying is no matter what compression you use, you cannot beat the physics of the problem. It is why the Iridium Sat's are LEO's to mitigate the problem.

A constellation of LEO's would be very suitable for voice (or VOIP) apps.

I once listened to to two (2) video production studios setting up a link through a GEO, using the audio channel to coordinate the set up. It was funny as the delay was causing them to talk on top of each other.

Exactly.

So when BPL comes to your area with kilobit speeds, will you abandon
your megabit technology for the same price? All the while, BPL will be
'peeing in the pool' to provide its sub standard performance.

In a pure sense, the radiator itself is.

It just may not be as useful in that application as an antenna of
another configuration that provides the system result being sought.

I like that last comment regarding mind set. Just look how people are
not viewing the subject without predisposition. No onw is willing to
deal only what has been proffered to the exclusion of every thing
else.
Everybody will use a text gained from somewhere to side line true
examination.
Stephan,. you
wanted out I took you at your word. I don't know how many times
This discussion will end the same as always, I don't understand what
you are saying
To heck with mathematics. Iknow what I know is correct.sSme will
change the content of what I state . And as always shown in history
ridicule is turned to when all other efforts fail.
But nobody will question the fact that all computor programs support
my
addition to Gaussian law to those of Maxweell. True, other scientists
concluded
that radiation is created via a time varience. No body has found
correllation to prove it
With a legitamate addition to a known law by Gauss I have given a
method where as
the hows of radiation is revealed that is consistent with Maxwells
laws.
The mathematics have been given that support it but they have been
swept aside
Existing programs support it but it is left to the user to determine
whether
"garbage in is garbage out" or to only accept what the program
supplies with

the appearance with known reality and junk the rest.
And make no mistake about it, when programmers placed an assumed condition
to a known law they did it with deliberation.
When it supplied error they covered it up by changing the program to concurr
with traditional thought. This is no different to when NASA ignored
what engineers told them about O rings and science was pushed aside.
Mathematical laws were broken and all that deal with these programs
are part and parcel of this mathematical fraud.
Best regards to all

To say that an AC current will not flow in copper unless it has clear
axis

access to the copper surface is balderdash. Cover the copper with an
insulator
with any thickness that you desire for safety incase you are in error
and then drill
into the center of the copper. Without a safe guard you will die!
What provides resistance on the outside als skin depth can by the
reverse contain current flow to the inside. You like many use the word
"tends"
with respect to external current flow. The word "tends" does not
make the current passage an undeniable fact. Yet you have hung
your hat on that premise. I repeat...balderdash

John, calm down a bit. You can't expect hobbiests who do not have the
skills that you have or even some who have managed to get though life
without an education to to follow the regimen of engineers e.t.c
were trained to follow. You have to accept that some will write things
just to part of this hobby group, just to be a part of ham radio
discussion.
And let us face it, ham radio is now the stage set up for auguements
for
arguements sake. A tack that is now followed by hams who have been
educated.
This group will never pursue the science of the hobby as they have
shown repeatedly.And all will present themselves a something that
does
not reflect their true status to be a part and parcel of a discussion
which may be totally insane. To make a point, ask the group why swr is
important.
Yes it is a medioche questuion but the thread will be extremely long

and
with an abundance of different authors which will then provide
arguement.
That is exactly what the hobbiest wants and is determined to get.
My sympathies to you

It just goes to show that I don't have an answer to every question
that you have in your efforts to supply a platform for your jeering.
I do know that a resistor stores energy applied while it changes to
heat.
I also known that the temperature change is not instantaneous thus
time
must be a factor depending on the environment. But you present
questions
that do not deal directly with the subject posed in your attempts to
jeer.
Look at your many exchanges with Dr John E Davis, you never did
provide an
instance where the subject in hand was incorrect or otherwise. Yet
your
exchanges with him were long and so disagreeable and disrespectfull
that after several attempts while remaining polite did not line up
with
an arguement that you often want he was forced to leave.The thread has
been provided again such that other can determine whether Dr Davis was
treated with respect by you
Actually nobody including you accepted his mathematics in any way
which he proffered in an effort to show that I was correct. The only
interest of this group was to treat him the same way that they treat
outhers
on this newsgroup. I will not respond to any more of your efforts

that
defray from the discussion at hand so that you can jeer.

The meaning of a time constant is not dependent upon steady state sinusoids
or transient; it is merely a characteristic that dependent upon the
physical properties of the components in the circuit.

You know that of course.

Let us say we design a power supply for use in consumer appliances. The
power supply of course has a capacitor across line and neutral for EMI
filtering, along with a bleeder resistor in parallel with this capacitor.
Together, the bleeder resistor and phase/phase capacitor filter have a time
constant. Now the time constant is meaningless with respect to steady state
input voltage (other than wave shaping high f emi components) and with
respect to transients. It is meaningful with respect to safety. If the
consumer pulls out the plug, the bleeder resistor must discharge the phase
to phase cap safely to prevent the consumer from being shocked when touching

the L-N pins. The time constant RC in this case MUST meet certain specifications, that is it must be less than 0.1sec. That is essentially required legally (since standard compliance is compulsory). The time constant exists is chosen for a worse case value, ie that the consumer unplugs the power supply at the peak of the AC cycle.

Actually, it is the DC discharge characteristic that we care about here. Transient suppression is not relevant nor is its ability to shape the incoming sinusoid.

Hi Ralph

I would sincerely like to know where to find that 2Meter beacon from a satellite. I have searched a little. Since you have knowledge of the satellite with the 2Meter beacon, I'd appreciate any link to it. I have some AMSAT journals but I havent recognized which satellite transmits that 2 Meter beacon.
Your posts show clearly that you question the accuracy of the radiation pattern measurement of an antenna when the satellite is used for the illuminator. I submit to you that you wont find a better way to record the actual radiation pattern. I can measure an antenna's pattern with close to 20 dB dynamic range. It is unclear to me why you doubt the accuracy of patterns I record.
One of the benefits of using 137 MHz is the ease with which a person is able to find programs that tell the exact location (Az - El) to the satellite. You can se an example of the radiation pattern at Patrik Tast's

site http://www.poes-weather.com/. The pattern is in the section "antennas".
I sure will appreciate any information you can give me related to 2Meter beacon satellites. I'm trying to make a program (free) that amateurs can use to record 2Meter antenna radiation patterns. I am very pleased with the program Patrik made for me using the 137 MHz satellites.

Thanks for your help
Jerry

This is another of your beliefs that not supported either by theory
or practice.

> The word "tends" does not make the current passage
> an undeniable fact.

I wrote "tends" because there is no discrete boundary near the outer surface of a conductor where ALL of the alternating current flowing near its surface is confined. But almost all of that current flows within several "skin depths."

The 1.8 MHz skin depth in a round, copper conductor is about 0.06 mm, which means that a tubular conductor with a wall thickness at least 3 times that can be used in place of a solid conductor of the same outer diameter, with no practical change in performance at that frequency.

OK, then.

A 1/2-wave dipole absolutely HAS more directivity than an isotropic radiator (and so does every other practical antenna).

But when any/all of them accept the same amount of power from an r-f source, then they ALL will radiate the same total amount of power.

So they are all equally efficient, by the classic definition of total power in vs. total power out.

Antenna directivity/gain is not a measure of efficiency.

Hey Doc,

Thanks for the input. I overslept for the 1300 UTC broadcast of VOK, but did pick up the 1500 broadcast. Unfortunately the RF amp offers nothing over the whip that comes with (and already attached to) my Sony 7600GR portable. More work to be done. Need to tease out the secrets of impedance matching, as well as add a boatload of additonal amplification. Damn it's hard to compete with a successful commercial product. Still, I have at least reached the level of performance with the RF amp that the preamp in my 7600GR already offered, with the exception of a little additional background noise.

Hope I didn't discourage Cecil from trying to help. Sorry if I did. I don't mean to be ignorant, and it is something I am trying to change.

73 and good DX

No mater how much amplification you have, if the antenna is not big enough or the proprgation is not good you will not pick up a station. There is a limit as to how much you can amplify a signal before the noise floor takes over. For signals below 15 to 30 mhz or so the noise floor is very high so not too much amplification can be used to help with the reception.

Most of the ham sats are simple as far as that can be. The antennas on them
are not really made to point that accurate.

Here are some sats that have beacons near 145 mhz.

http://www.amsat.org/amsat-new/satellites/satInfo.php?satID=2&retURL=/satellites/status.ph

I read thru all and it wasn't until thelast sentence did you state
anything that is relevent. The Dc discharge characteristic
when the terminals are shorted. Discouting the spike at the
beginning the discharge is dependent on the size of the vessel
and restrictions applied by the circuit. The larger the vessel
the sharper the curve with respect to time. This goes for both
the inductance and the capacitance and it is only the losses
which are small take away the perpetual motion.
I suggest you go to google and look up a "tank circuit"
where they will I am sure take you thru the phase changes
that create the pendulum like action.
But then you knew that all along, anything but review the math.
Hot air once again. Why not discuss it with the broadcast engineer
with his long time service at switching on a transmitter every
morning,every day
plus turn the lights out. As Vanna White would say in defence of her
salary status
You have to know the alphabet
Art
Art

Richard Fry wrote:
"Read Terman`s RADIO ENGINEERS` HANDBOOK, 1943 edition, pp 30-31 for more on this (or many other sources)."

Amen. Terman doesn`t say different things in different places. He is consistent. In Terman`s 1955 edition of "Electronic and Radio Engineering" he writes on page 21:
"It is to be noted that some of this (magnetic) flux exists within the conductor and therefore links with, i.e., encircles, current near the center of the conductor while not linking current flowing near the surface. The result is that inductance of the central part of the conductor is greater than the part of the conductor nesr the surface; this is because of the greater number of flux linkages existing in the central region.

That`s why we have skin effect and why hollow pipes carry HF current as effectively as solid rods with the same external surface area in most cases. The pipe`s interior doesn`t carry current unless its diameter is at least 1/2 wavelength (its cutoff as a waveguide).

Best regards, Richard Harrison, KB5WZI

Here, let me verbalize the problem which he is putting forth.

The relay station, i.e. the GEO satellite, is too far away to allow conversations to exist in a way in which we are accustom. The participants would mis-queue their conversation and speak on top of one another.

No amount of educational sanctification is going to change the speed of light.

Chris

As I told you once already, the last 30 years of my professional background was in the field and applications engineering groups of the two largest designers/manufacturers of broadcast radio and television transmitter and antenna systems in the US: RCA and Harris.

My experience working directly for broadcast stations was early in my career, including with a stint at WJR, a 50 kW, non-directional AM station using a 195ï¿½ monopole (700 ft high).

And what is your commercial experience in the field of r-f systems?

726. Inverted VEE Yagi antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2007-11-11 20:26:13 UTC
From: WA4SZE@gmail.com
Message-ID: <1194812773.482962.156660@k79g2000hse.googlegroups.com>
Source record: 34079

Greetings!

I would like to build a 2 element inverted VEE yagi antenna. I
have seen this type of antenna in a SWL publication.

I would like the Yagi to be used on 7 mhz

I am seeking opinions as to the performance of such an antenna

The driven element will be a 7 Mhz half wave dipole (66 feet total)

The reflector element will be about 5 % longer

The spacing of the reflector will be about .20 wave length. about 26
feet from the driven element.

The angle of the vee will be about 55 degrees .

The feed line will be open wire 200 Ohm feed line to a true balanced
tuner.... no baluns truly isolated tuning network just like the
1940's you know, the tank coil type with an adjustable link in the
center of the tank then up to the driven element.

I know that the driven element impeadance will be low so I will use
3/8 inch aluminum power line (ACSR cable) for all of the feed lines
and elements.

The terrain under the antenna system is a 'cow' Pond that has water
in in most of the time, the terrain is low and is alway wet.

Please provide your thoughts on this antenna

Thanks !!!

Dave WA4SZE

> I read thru all and it wasn't until thelast sentence did you state
> anything that is relevent.

I really am trying to find out in what way that "time constants" are relevant to your hypothesis or theory or whatever it is. I am surprized that i hit something relevant. Now, you were talking about the time constant of distributed capacitance and inductance with resistance along an antenna radiator. I was thinking about this and I do think there "may" (or may not) be some interesting concepts when considering an RC or R/L time contant when the "R" is "radiation resitance"...it could be fun to think about and I will ..

But Art, how can what you have posted help me to understand why electrons jump off the antenna wire (they are very smart because they know just when and where to jump) and cause an effective phased array of guassian static antennae that line themselves up in maxwelling time varying electric and magnetic fields propagating at the speed of light, at least until gravitational forces take over and they hit the ground :-)) ? Pardon me if this sounds ridiculous.

That is why I say, please show me the math for whatever it is you are proposing.

Geeze, come on Art...

> where they will I am sure take you thru the phase changes
> that create the pendulum like action.
> But then you knew that all along, anything but review the math.

> Hot air once again.

Well, it all comes from the heat stored in the resistor when the distributed capacitance along the antenna discharges in the ohmic resistance in your 50 ohm antenna :-))) (god this is getting ridiculous)....show me your math.

> Why not discuss it with the broadcast engineer

You mean some guy who learned electronics in the Navy and he 'knows all there is to know and what he don't know ain't worth knowin' anyway'? Your theory supposedly rises about all that! Now show us the math.

wow, heavy stuff to build a beam like that with. how high will the apex be?
my first impression is that the angle is a bit small, can't you spread it
out some more to get 90 degrees or better?

John'
Is there any place in the U.S. that BPO is active and sanctioned as
meeting all rules applied?
I have heard of testing areas that were shut down because of
interference to mobile radio's
but to the best of my knowledge none have met the rules imposed by the
FCC.
Please educate me as to where BPL is active and sanctioned by the FCC
as abiding by their rules
and now is a going concern with respect to being a business.
Many thanks
Art

Area(s) in Texas/Virginia and more ...

The past posts I have made here make reference to some ... or, an internet search will quickly disclose some ... most, probably all, are just testing areas.

Actually, their is only one area where satcoms fall flat on their face--data exchange intensive apps. which MUST occur in REAL TIME--i.e. state of the art interactive games. The old farts here need not be concerned ...

For everything else there are viable work arounds--well, the targeting and control of cruise missiles is another--but one the general public can ignore and allow the military to apply their work arounds ...

What the hell are you doin' with a amateur license then, the =>1/2 delay on am/ssb/fm/digital-packet transmissions must drive you loony (no relation to the canadian currency :-))

You play a LOT of interactive games?; well then, you have just sited the only application where the delay becomes of notable importance!

By all means drop out. Until somebody comes along and faults the math
I am
doomed to accept it.
Please please do as you said, that you can handle the math and prove
it in error
so I can remove myself from this mess.Many have said they can but none
have
shown that they are capable Considering all the postings on this

subject
there must have been somebody who can actually do mathematics so why
are they
reluctant to come forward. Is the math really to difficult for the
average student
or is there some fear associated with it that imposes silence?
We have college teachers among this group so certainly if it was in
error they would be quick to say so. Doesn't their absence bother you?
Just state that the math is in error as presented by Dr Davis and why
then
everything comes to a halt.
The subject which is causing anger falls completely apart when that
fact
comes to light.You ask for the math and I give you the math, what's
holding you up?
Subject closed until the math is subjected beyond the past peer review
which
states that it is accurate and correct.
Talk is just not capable of destroying the truth of mathematics.

That`s an I dare you.

Roy may tell us if EZNEC needs Art`s embellishment for accuracy.

Art did not answer my question of Nov 8, 10:27am in the "An instructive trick" thread. It was: "why would we use the time constant without the angular frequency?"

On page 904 0f the 3rd edition of Kraus` "Antennas" is found:
"The availability of computers in the 1960s provided antenna designers with an alternative. They could develop software to simulate the performance of antennas. In general, these techniques either numerically solve Maxwell`s equations by descretizing the problem using integral techniques, such as Moment Methods (MoM) as discussed in Sec. 14-11, or differential techniques, such as finite elements or finite difference-time domain."

Best regards, Richard Harrison, KB5WZI

Art's position apparently states that hams' antennas do not properly take into account (therefore, I suppose, optimize) the actual behaviour of charged particles moving through a medium such as an antenna. Furthermore, Gauss's static laws can be used as an adjunct to fully describe this behavior. (True, as noted below, but so what?) In reviewing the archives, I believe the following post from Davis is what he uses for confirmation that ham antennas are not properly designed "correctly" because we all follow a herd mentality. However, all Davis seems to be saying is that at a given time of observation of a dA 'surface', the Gaussian static calculation will hold true for moving particles during a snapshot where the delta t = 0. In the calculation he happened to review earlier, he confirmed that during a particular time interval the surface integral of the E-field over the area (facing outside the surface of the cyclinder) was equal to (constant) times the integrated charge density over the volume (inside the same portion of cylinder).

The E-field immediately inside the area = the E-field immediately outside and it is proportional to charge density time volume inside (or charge). Yep, that's gauss's law.

No surprise, right?

So what is Art trying to prove? That the dynamic real-life case is an infinite summation of static cases over time? Big deal. We know this already Art. What am I missing?

I am getting very close agreeing with Dave: This is a big "so what?"....which probably explains why Davis dropped out of the thread.

Quote from Davis========

div E(x,t) = 4\pi\rho(x,t) (Gaussian Units)

If you integrate this over a closed surface, and then use the divergence theorem you get

\integral dA.E(x,t) = 4\pi \integral dV \rho(x,t)

The integral on the right-hand side is 4\pi times the total (time-varying) charge enclosed by the surface. The other equations are also valid, including the one you wrote.

Coincidently earlier this morning I was reviewing the derivation of the energy loss of a heavy charged particle as it passes through matter. The derivation made use of a very long cylinder with the charged particle traveling along the axis of the cylinder. One point in the calculation required the integral of the normal component

electric field (dA.E) produced by the charged particle over the surface of the cylinder. That is, the left hand side of the above equation. The answer is given by the right hand side of the above equation. In this case, the charge density \rho(x,t) was created by the moving charged particle.

An inverted vee with that small an included angle will be narrowband and have a low feedpoint impedance. Coupling from the other element will further lower the impedance and narrowband the antenna even more. The wide spacing (for a Yagi) will mitigate the latter somewhat, but it'll still occur. The wire size you've chosen might be adequate to keep loss reasonable, but there's nothing you'll be able to do about the very narrowband property. Not only will the impedance change rapidly with frequency, but so will the pattern. Typically, front/back ratio deteriorates much more rapidly with frequency than gain does, so you might or might not get a usable bandwidth if gain is your only goal. I highly recommend modeling it to see what it'll do before you expend the effort to put it up.

this sounds good.

you said you can model a helix over an infinite ground plane in
eznec? What are you powering it with? a coax? if so, you have one
conductor connected to the helix, and the other is where? this is the
source of my confusion, i guess.

What Terman says is true, for the particular example that he chooses. But it may leave an incorrect impression that the conductor needs to be completely encircled by flux linkages.

In fact the skin effect will develop on the surface of any conducting material of any shape, wherever there is RF current flowing.

Here is a link to a detailed mathematical proof, from 'Transmission Lines for Communications' by C W Davidson (Macmillan Press, 1978, ISBN 0 333 32738 1): http://www.ifwtech.co.uk/g3sek/misc/skin.htm

Davidson's analysis starts with the most general assumption possible: that RF current is flowing over any small patch of a conductor's surface. No assumption is required about the reason for the RF current to be present, only that it is. Likewise no assumption is required about the cross-section of the conductor, only that it has an exposed surface (and by implication, that there are no constraints due to a small radius or insufficient depth). Davidson then derives all the usual equations for the skin effect. The only drawback of this derivation is that it is highly mathematical, and difficult to put into words; but it's still physically correct.

To repeat, I am not saying that Terman's explanation is incorrect; only that the skin effect is a far more general phenomenon than his particular examples imply.

This is important because, by taking the existence of the skin effect as a guaranteed starting-point, the explanations for the behaviour of coaxial cables, 'bazooka' baluns, 'shielded' loops and many other devices will all fall neatly into place.

Hi Sean

I can make a helix with EZNEC very easily. I located the ground end of
the helix slightly away from ground. A short wire from the ground end of
the helix to ground becomes the feed.
Contact me at my E-mail and we can try your dimensions.
I'd sure like to learn to maneuver in 4nec2. This may be a motivator so
I can get more familiar with 4nec2

Hi All,

"What is so" is that both Arthur and Davis used the same term of
Gauss' Law. The joke is they both forgot to read the fine print that
it was Maxwell's equation, not Gauss, and that Maxwell had merely
brought Gauss up to date to include time (something Arthur is claiming
as his own discovery); and then to honor Gauss, Maxwell named his own
(that is Maxwell's extension of Gauss) equation as Gauss' Law.

Of course the math is right, Maxwell proved it, and we've been using
it for 3 centuries now.

Gauss's law IS one of Maxwell's equations. In fact both Ramo Whinnery and Van Duzer's "Fields and Waves in Communications Electronics" (pg 237 in the 1st edition) and Jackson's "Classical Electrodynamics" (compare pg 2 and 33 in the 2nd edition). So every time art makes that assertion he is just showing his ignorance of the facts.

I recommend you give up the argument with art, its hopeless... As you know,
but art obviously doesnt, Gauss's law IS one of Maxwell's equations. In
fact both Ramo Whinnery and Van Duzer's "Fields and Waves in Communications
Electronics" (pg 237 in the 1st edition) and Jackson's "Classical
Electrodynamics" (compare pg 2 and 33 in the 2nd edition). So every time

Dave, You might want to consider an alternative: an inverted vee phased array with .125 wave spacing, having equal lengths of coaxial cable to the shack. You can build a small enclosure with a switch and enough coaxial cable to produce 135 degree phase shift. The switch can be set up to reverse the array and a center position (maintaining equal lengths of feedline) will allow both antennas to be fed in phase, resulting in a nearly omnidirectional pattern. You'll get about 3 db of gain with a nice null directly off the back.

I used this scheme to advantage when I lived on a city lot in Cincinnati for a number of years.

Hi Stefan -

For some reason I'm not seeing your posts on r.r.a.a. The only way I know you've posted anything is when someone else quotes some of it in a response.

A few months ago I could see your posts using my Outlook Express NG reader and normal NG server, but lately they are not showing up.

Do you know why this is happening, and how it can be fixed?

Thanks,

Rich (RF)

Art wrote:
"Yes, and both will defend the antenna programs to death even they cannot point to the time variant that is implicit in Maxwell`s laws."

Impliciit? Wrong word, it is explicit.

Maxwell`s field equations fully regard the variation of time. The first equation is directly derived from Faraday`s law of electromagnetic induction. Faraday discovered that a magnetic field which varied with time was essential for induction between coils.

Faraday`s law is: Volts induced into a coil = (number of turns) d(phi)/dt (constant).

Where the constant is (-1) and d(phi)/dt is in webers/sec., the generated emf is in volts. A weber = 10 to the eighth power maxwells.

Best regards, Richard Harrison, KB5WZI

Yes, that's what it looks like to me too.

Art, from our very own rec.radio.amateur.antenna, is bringing maxwell's
equations up to date by including gauss's static E law with gauss's
magnetic law, and the faraday and ampere laws that handle variations with t.
Most importantly, antennas modelled on the Art-Gauss extension also agrees
with ham antenna computer programs that are based on the "original" maxwell
laws. Amazing. (I get it now) ;-)

Hi, Designing a 33' portable 80M vertical. Modelled it, and said I needed a 37 uH loading coil around halfway up. Wound one using a 2" cardboard form and #18 teflon insulated wire. My Z meter said it was 37 uH, upon placing in service, the resonant point was fairly close to the design point on the antenna.

My question: I was hesitant to to put the coil in service because my MFJ259B would not confirm the inductance value. It said the Z of the coil was > than 650 ohms or that L(X=0), all dependent on frequency. I could never get a good indication of the Inductance. I suspect this is due to self resonance of the coil, but don't know. I calculated the Inductance of the coil given the F and Z reading on the 259B and it came close to 37uH, but still (inductive reactance) X=0. Anyone know what is going on?

Thanks,
Gary N4AST

You cannot get an answer to the question you asked (i.e., how does time constant relate to waveforms?) because time constant is dependent only on physical component properties like capacitance, inductance, resistance etc..

There is nothing in "time constant" that relates to frequency, transient rise time etc..

It is not related. Ask any ham. That is my answer.

"Gauss`s law IS one of Maxwell`s equations."

Yes. I`ve suggested Kraus to Art but he seems not to have pored through Kraus yet. On page 395 of the 3rd edition of Antennas is a table of Maxwell`s equations in integral form. One column is from Ampere, another from Faraday, and the last two are from Gauss.

Art wrote:
"Same question, but now look at distributed inductaance and how that works!"

On page 2 of Terman`s 1955 opus is written:
"The strength of the wave mmeasured in terms of microvolts per meter of stress in space is also exactly the same voltage that the magnetic flux of the wave induces in a conductor 1 m long when sweeping across this conductor with the velocity of light."

Remember reciprocity and the fact that only a perfectly matched antenna can extract as much as half the power in the wave. The antenna`s radiatiation resistance acts as a Thevenin source when receiving and reradiates the other half of the power received but not delivered to the load.

The description of magnetic flux inducing signal into a receiving antenna may be the cause of describing transmitting antennas as creating from current in the wire a magnetic flux around the wire which almost simultaneously produces an electric field which almost simultaneously produces a magnetic field ad infinitum.

Best regards, Richard Harrison, KB5WZI

Hello Rich, I am not sure except to surmise that my ISP's usenet server may not be forwarding to the google server as fast as it is to the other usenet servers. I would have thought the google server would be among the first to be forwarded. I did change to a hotmail ID in case google's server checks for email id resolution issues (I refuse to use an 'active' email ID anywhere on usenet). Thanks,

A Time Constant is also the -3dB point in a frequency response, hence
there is a frequency relation.

A Time Constant is proportional to square root of the rise time of a
transient, hence there is a transient relation.

769. Open Loop aka Dipole bent into a square

Newsgroup: rec.radio.amateur.antenna
Date: 2007-11-12 04:06:39 UTC
From: Priz <dapriz6@yahoo.com>
Message-ID: <1194840399.691182.318450@50g2000hsm.googlegroups.com>
Source record: 34022

I'm pressed for space outdoors so right now, I'm working with attic antennas and need some help.

I was able to put a 60 foot loop of wire into my attic and am not having much luck getting it to load up. I configured the loop as an open loop, aka a dipole bent into a rectangle which is open at one corner and fed with 300 ohm twinlead at the other. I'm using an MFJ 911H 4:1 and 1:1 balun to tranform the twinlead to coax and a homebrew antenna tuner.

Using an SWR analyzer, I find the only place I can get low SWR is near the 15 meter band and some frequency ranges above it, like 6meters and 2 meters. I was hoping the 60 foot length would help me get down to the lower bands with some compromise, but at least I was hoping to get there. The transmatch, which consists of 2 capacitors and 2 inductors isn't any help at all. I've used it in the past to load up random wires and such, but this project doesn't seem to be working.

Anyone have any experience with this sort of antenna? Let me know what it is I'm doing wrong.

Any advice is appreciated.

Hey Ralph, thanks for coming in. I am wondering though if I can't tune out some of the noise,and eliminate more with a directional antenna (which I currently don't have.) Would an IF stage not help me here? Or a second tuning function, on the output? Just wondering.

Do appreciate your comments. If I'm wrong I'm wrong, I was just thinking these things might help. No? The signal I am trying to clean up is at 9335 kHz.

I spent a good part of my career as part of a team designing samplers, step generators, TDR systems, and associated circuitry with rise times down to a few ps. Among the projects I designed were two delay line compensators which compensated for the distortion of a fast step by the skin effect loss in transmission lines (one to 2 GHz bandwidth and the other to 9, both to very high precision). These designs were used in production Tektronix instruments. I also often helped the customer support group with difficult TDR application problems, and I wrote and taught several classes on TDR techniques. One of the many skills necessary to succeed at this was to gain a very good understanding of rise times, time constants, frequency responses, the relationships among them, and the physical factors which influence them. From that background, the discussion in this newsgroup seems to be taking place in an alternate universe. I feel out of place there, so I'll leave it to its usual and rightful inhabitants, and bow out.

Time Constant is "related" in terms of these things. They are not part of
the basic definition of tau but they are related. Your's is a much better
answer to the (original) question than mine.

One needs to understand how the 300 ohm twinlead
transforms impedances and why a 4:1 balun is probably
not a good choice. One could model this antenna and
feedline with the free demo version of EZNEC
available at eznec.com

Hi Rich

A further thought.. (Seeing that you have two issues)

Yes a 550 errmsg basically means no mailbox found for that user. This is a common thing when reply to newsgroup addresses for reasons outlined by others.

The reason for the non visibility of the post could be a slow NNTP (news) server as Stefan mentioned. It might also be possible that your server (or a feed to) is validating the senders reply address. This would be highly unusual as using a valid reply address on a newsgroup is generally asking for spam trouble.

Validating a reply address for normal email is used in quite a few systems as a spam prevention method. Maybe the sysop of the news server has tried to employ this on their news server? You could ascertain this by checking if any other posts from rr.com (the same server as Stefan's) are coming through.

Another possibility is that your newsgroup server completely blocks feeds from certain others that are known to be spam etc sources. Blacklisting mails servers is quite common so I expect (but haven't checked) the same applies to news servers. I haven't looked into any of this but it would be fairly easy to research.

Apologies for the length.

Cheers Bob VK2YQA

When a wire flattop is fed with parallel line, what are the affects on the system when the feedline is not perpendicular to the flattop? It would seem to me that the system, consisting of flattop and feedline is no longer balanced, and the feedline will radiate on transmit and pickup local noise on receive.

Any comments will be appreciated.

Dave,
Would another 'IF' stage, or filtering, or 'nulling', or whatever you want to call it, help? Sure. But then you start running into the 'practical' thingy again. It can get sort of complicated deciding what is 'noise' and what is desired signal. DSP does a lot of that when told how to do it by the controlling algorithms (or is that 'Al-Gore-isms'? sorry, I know better, just can't help it). The mainest problem is the time it takes to do that, it is not instantaneous. And if you are going to make that controlling algorithm variable, the time it takes makes things even more time consuming, not to mention difficult. Keeping in mind that simply making the antenna larger/longer can do about the same thing at less expense (time/work/$$$), why not? Easy to do with a recording (sort of), very difficult in real time. Manually doing all that is almost impossible. How do you decide what to 'do' before it's too late? There are limits with today's technology. So, put it off till 'tomorrow', right?

Essentially correct but common-mode chokes and/or
link coupling can help. And it's not just a parallel
line problem. Coax that is not perpendicular to
the flattop suffers essentially the same problem.

Hmmm. Yeah. sigh Point taken. I guess this is just my hobby, and I really don't have anything better to do (other than housework.) I don't know what to say. Guess I just have to prove to myself that everything that can be done has been done, or that it's not worth the effort for the outcome. sigh again.

I do appreciate all of the feedback, and the patience with my ignorance. I am trying to make this thing work off of a whip for portability's sake, and am just not willing to accept defeat yet. May not be much longer though... It does work great on the external antenna, I just want it to work better off of the whip.

Thank you, all of you who replied. And thank you, doc, for the final simple analysis. I don't mean to be stubborn, I just have to try everything to prove to myself that it is as good as it can be. Sorry. Guess I am stubborn after all.

The hand-holding is appreciated. Sorry if I frustrated you guys. Thanks again for your patience.

What's the easiest method of determining which antenna works the best for a particular situation? Simplest answer is to try it and see (experience). Then again, what happens when that 'situation' changes? Hmm, try something else? Great answer, isn't it? Very helpful, right?
There is no 'best' answer for all situations unless you do some very comprehensive testing, with some very expensive equipment, done by people who know what they are doing. That 'best' answer is still a 'maybe'.
So. A "Can you hear me now?" tends to work well. Accept the fact that there are always going to be times when everybody isn't gonna hear you. That's what relays are for (the 'INFO' line on a message header?). For almost any range, but especially for VHF/UHF, higher is usually better. Produces more usable range than the antenna design (within reason!).
Everybody wants the 'best'! Very few, except in particular instances, ever get it.

783. reducing chance of lightning hit on a vertical ?

Newsgroup: rec.radio.amateur.antenna
Date: 2007-11-12 14:33:10 UTC
From: Nick <a@b.com>
Message-ID: <GuZZi.11390$ib1.2369@newsfe3-win.ntli.net>
Source record: 34036

Hi,
I want to install a vertical, fed with an SGC230 at the bottom, but concerned about minimising chance of a lightning strike on a bare conductor.

Would it give more protection / solve the problem, if I encased it in a fibreglass yacht mast which I happen to have ?

I plan it to be approx 40' high with the top 25' being a fibreglass yacht mast with the wire running up the inside. Top would be insulated / sealed so no ions could spray out, attracting a strike ... am I going the right way ?

Thanks,
Nick

Source record: 34037

Jim,
Yes, they are loading coils. Specifically 'where' they are in the antenna is very variable, just depends on the particular user, what he has available, etc, etc.
One thing you should be aware of is that translating between 'CB' electronics and everyone else's electronics is not always easy! The 'CB' world has proven that all the 'acceptable' assumptions assumed by the rest of the world are mistaken in at least some way. Obtaining an acceptable translation is very "iffy". (Nicest way I can think of to say it's mostly total B.S., sorry.)
Examples:
Wider coil windings (straps) radiate better because or larger surface areas, than measly small wire.
Wide coil windings that are 'flat', horizontal, radiate in a horizontal polarization.
Vertical strap coil windings radiate in a vertical polarization.
'Fat' antennas can radiate gazzilions of watts whereas 'smaller' diameter antennas can't.
MY antenna is better than your antenna because I made that way.
... I quit. Probably gonna make someone mad or something.

Hi Nick,
There is virtually nothing you can do to prevent a strike hitting your antenna. But you can attempt to pursuade Mother Nature to send the damaging electrons somewhere where they won't do damage. Get a Polyphaser or ICE or other good lightning arrestor made for this purpose and install it with a good ground under the antenna. Your objective is to divert the strike around your equipment and into the ground, taking the path that YOU provide for, not the one that the lightning strike would otherwise select. Your ground must have the capacity to absorb the electrons which arrive in massive quantities in a few microseconds, otherwise they will give up on you and find their own path to ground, often not the way you would prefer.
There is good information on this technique on the polyphaser website, probably www.polyphaser.com. Most likely you will get about 50 more replies so be prepared, this is one of the favorite and most often discussed topics on this newsgroup.

Nick

With the voltages involved in a lightning strike, the fibreglass mast will not make much, if any, difference. Rain fall and dirt deposits will create a conductive path along the mast a few days or weeks after it has been erected. Lightning is attracted to the highest pointiest thing in an area, no matter what substance it is made from. Churches and trees are made of insulating materials and they attract more strikes than anything else on land. It was common to have to regularly rebuild the towers and steeples of medieval churches before lightning conductors were installed. The average steeple usually lasting no more than a century before suffering catastrophic damage from a lightning strike. At the time, this was just accepted as a sign that the parishioners were insufficiently pious, or had transgressed in some way.

The fibreglass mast is ideal as a support and to provide weather protection for your antenna element(s), but do not count on it reducing the chances of a lightning strike it it is the tallest structure within 400 yards or so. Various tables and maps are available on the internet showing the frequency of lightning strikes per year per square mile or square kilometer for most areas in earth. These should help you evaluate the risks in your particular area. Forty feet is not particularly high and if you live in an area with less than 20 lightning days per year, I would evaluate the risk of a strike as being low. There is always a statistical risk and that's a chance you have to accept when dealing with any force of nature.

Try to ensure that there is a good earth connection at the base of the vertical antenna using earth rods and/or buried radial wires so that in

event of a strike, the lightning energy is dissipated into the ground rather than transmitted along the feedines into your house. A switch to disconnect and earth the antennas when equipment is not in use is always a good idea. A look through the MFJ catalogue will give you an idea of what equipment is available.

> Any advice is appreciated.
==========
Instead of using a balun and asymmetric matching unit (transmatch) I
would suggest you use a matching unit to suit a twin feeder directly
,like the EZEE Match or the Link Coupler as per the ARRL Antenna Book of
which I do have the 18th edition ,where the coupler can be found on
pages 25-11 and 25-12.
A variety of matching units to suit twin feeders can also be found on
the web site of PA0FRI.

In your current setup you could use a 1:1 Balun and clip a current
sensor on 1 lead of the twin feeder to determine where there is a
Current maximum for a mid-band frequency . For this purpose you might
have to extend the twin feeder and coil the extension inside the shack.
You would then possibly need a different length coiled up extension for
different bands.
Have a look at Cecil Moore's Web site .

You'll not get a straight answer to that question because the FCC is
applying their rules in a manner that has become the subject of
litigation by the ARRL. In essence the FCC says BPL is not an
interference problem to mobile stations because they are able to leave
the area. There are other points of contention, but this one makes
any reference to "sanctioned by the FCC as abiding by their rules"
meaningless.

Hi Nick,

No, it wouldn't.

Make the antenna shorter, and surround it with taller, nearby grounded vertical conductors for the lightning to select in preference. For more protection, connect the tops of the taller conductors over the antenna.

Of course, this advice reduces to putting the antenna in a grounded cage that takes the hit. Unfortunately it also renders the antenna deaf.

Moral: Trying to stop the lightning from hitting your antenna also stops RF.

[Hint: if you are going to stop it with a super glom of insulation, like fiberglass, consider that this insulation is inferior to a bajillion miles of air already there surrounding the antenna. That doesn't slow down lightning much does it?]

This statement doesn't tell the full story. Others who would have
severe problems with BPL are not (currently) affected because those
testing BPL have notched out their bands. They will be concerned as
soon as BPL affects them... which will be never because they're big
enough to kill it dead in its tracks. Among those notched are the
public service/safety bands, military, and essentially everything
important to the govt.

What BPL profits? The ones projected based on *present* DSL and high
speed cable pricing?

Not the point. The point is that your figure was only half the real
delay.

>You play a LOT of interactive games?; well then, you have just sited the
>only application where the delay becomes of notable importance!

No, I don't play interactive games. And it's noticeable (and
objectionable) in conversation. It doesn't produce a level of
performance the consumer sees as being a high quality experience...
thus it's a problem.

(Spoken in Columbo's voice and mannerisms)"Uh, podden me, Cec, butta,
12db improvement compared to what?"

A 108" whip tuned with an electronic autotuner at the base, on the
trailer hitch attached to an average car should be just as (was gonna
use the words efficient and effective - but thought better of it) as a
short little whip mounted in PVC pipe at the same location, but using a
mechanical tuner (screwdriver) instead of an electronic autotuner such
as an AH-4.

Yes, I have considered a screwdriver antenna, just don't know where to
put it on my minivan(s).

As you can tell, I'm coming in late on this one. Thanks for your patience.

I agree with Rick.

Additionally, don't forget that your homeowner's insurance policy will usually reimburse you for damage incurred via lightning strikes. But be sure to see it in writing. Personal assurances from your agent are not enough. Have the agent show it in the writing of YOUR policy, or one identical to the one that you will be purchasing.

The last thing that you need after the damage is done is for the insurance company to try to wiggle out of covering your lightning damaged equipment.

Try routing the wire around the attic so that the opposite ends are as far
apart as possible, rather than in a loop. If you have the height, mount the
feedpoint at the apex of the roof and take the wires towards the ends of the
attic. Then bend them around to follow the roof and floor line. I found this
worked more reliably for me than a loop. An ATU feeding a twinline feeder
through a 4:1 balun should be able to load this up on all bands. You could
even try feeding it via an ATU and coax directly provided that you wind a
few turns of the coax feeder around a ferrite rod or ring by the feedpoint
to reduce pickup and RF current on the coax outer. Make sure the ends of the
antenna are well insulated, they will be at high voltage.

I use a closed loop of approximately the same size. It is corner fed with coax (don't know the length...probably about 20-25 feet). A MFJ tuner is at the rig, and will match it all the way down to 80 meters. However, performance is very bad below 14 Mhz.

So my suggestion would be to first try closing the loop, since this is a pretty easy experiment with a pair of alligator clips and a piece of wire. Next, you might change the feedline length to give the tuner a try at different feedpoint parameters.

I do have a lot of induced RF in the attic wiring. You might use RF chokes on solid state heat/ac thermostat wiring to prevent damage. Good luck.

Exactly right. Either end the helix on the ground plane and put the
excitation on the first segment of the helix, or create a short segment
that connects the helix to the ground plane, and put the excitation there.

The trick in modeling a helix isn't the helical part, it's the ground
plane. Radial wires with circles, a rectangular grid of wires, etc.
For simple hacking, just point the helix straight up and use a perfectly
conductive ground.

Hi Ed,

This is a bit garbled, but the sense is there.

You are comparing a bad installation to a bad installation - yes one
will be as efficient/effective as the other.

The tuner at the base of the whip has invested resonance in the wrong
place. A coil at the base of a whip also invests resonance in the
wrong place. A coil higher in the whip invests resonance in the
better places by degree.

Ostensibly, the premium degree of coil placement is one half to two
thirds the way up the whip. A screwdriver antenna attempts to make
this resonance investment. If you will note, the coil section falls
between a lower tube and an upper whip.

There is a world of discussion as to why it is better that I will
leave to others to fill in.

The popular solution seems to be the Alpha-Delta grounding antenna
switches. Unfortunately, There does not seem to be one that can be
operated remotely.

Sort of true..
One can find the equations at http://home.earthlink.net/~jimlux/hv/fuses.htm

Onderdonk's equation takes into account the time course of the pulse,
and is probably more relevant here. AWG16 for a 10 microsecond pulse
melts at 12.6 kA. AWG6 is 100 times the size, so one might expect 1.26
MA fusing current.

HOWEVER.. in a fast pulse, the current is carried only in the surface of
the conductor, which Onderdonk's and Preece's equations don't deal with,
nor does the simple approximation in EETimes.

Also, for fast high current pulses, the magnetic fields are important:
a) because of the forces on the conductor which tend to deform it and b)
because of the effects of inductance.

Note also that the code also allows oddball stuff like AWG17 copperclad
steel for the grounding conductor. I surmise that the sizes are chosen
more for mechanical ruggedness than for current carrying capacity.

It is true, however, that a short length of AWG6 can carry a typical stroke current without fusing or failing.

I would venture to guess that any of the popular designs will be within
a dB or so of each other. Your bigger concern will be system issues
like cost, feedline losses, construction time, etc.

You might look into some form of collinear array (multiple half waves
stacked on top of each other) because you'll get more gain at the
horizon and still have an easy install. There's lots of these in all
the commercial catalogs (e.g. Tessco), and there's a few in the ARRL
antenna book if you want to build something.

This is a bit of a challenge to make accurate to 1 dB at 144 or 440 MHz.
The leakage around the switches, etc, is difficult to deal with.

You're probably better off scrounging for a decent surplus/used step
attenuator made by someone like Weinschel or HP.

Did you have the test frequency set to a point in the 80M band on the
MFJ 259? The operating frequency does affect the measured inductance.

If it is not too much of a hassle, put the antenna into a temporary
operating position and put the analyzer at the feed point to determine
if things are close.

The Q of the coil is going to be important if are to achieve an SWR
below 2:1.

A quick run of the numbers indicated you need 43 turns of #18 wire on
a 2 inch form that is 4 inches long.

Since you did not specify the diameter of the mast, I choose 1.5
inches which computed to a resonant point of 3.375 mhz.

You may find my experiment at
http://dixienc.us/28FtVert/28FtVertical.htm
interesting...

Source record: 33964

>I am seeking opinions as to the performance of such an antenna

The opinion is it will be a great antenna.

The modeling facts are:
It will give you approx. 11 dbi gain, and 13 db f/b. It will have a feedpoint Z at resonance (7.025 MHz) of 33.3+j0.

The gain will vary from 11.24 dbi at 7 MHz to10.2 at 7.2
The f/b will vary from 12 db at 7 MHz to 9 at 7.2 (peaking at 13.6 db at 7.05 MHz)
The feedpoint Z will vary from 30-j6 at 7 MHz to 50+j33 at 7.2

The parameters of this particular antenna are:
ht above ground 23 meters
Length of one side of driven ele = 10.3 meters
Length of reflector = 10.66 m
spacing = 6.7 m
angle between legs=120 degrees

There are of course hundreds (no, thousands) of different combinations of these parameters that will give different performance characteristics. This one is not necessarily optimized for any particular objective.but it is close to what you said you want to build. Naturally I highly recommend that you model your own antenna and see what changes affect what !! I'd be happy to give you my 4NEC2 file that I used to determine the above. It and the program are free. It would be a great starting point for you.

Interesting observation - I have made similar trial runs for others who have inquired on this newsgrouop, and the tower reflector, and always offer to send my file and offer to help get them started in modeling (10-20 minutes on the phone with both of us looking at the same data in the program). To date no one has either acknowledged my postings or accepted my offer!! Is modeling that intimidating? I learned what little I know by hacking around for hours. I could teach someone what I know in 10 minues if they were interested and computer literate, short circuiting many hours off the learning curve. Modeling is fascinating. All the tradeoffs that Roy just aluded to can be studied easily on your own PC without taking the word of others. You can change the angle, the height, the ground under, the dimensions,the size of wire, the spacing. You can examine the gain, f/b, pattern, imedances, takeoff angle, bandwidth.
And I will GIVE you the simple little file that you load into your own free copy of the modeling program that allows you to do all of this.

An open loop is supposed to be 1/2 wavelength. A closed loop is supposed to be 1 wavelength +. A closed loop will sort of work on EVEN harmonics. Using a 4:1 balun is probably wrong, as is the 300 Ohm line. For 20 meters you would need about 72 feet of wire in a closed loop, 1:1 balun, and 1/4 WL of RG11, feeding into a random length of RG8. SWR will be less than 1.5:1 at resonance. For 40 meters you could use about 65 feet of wire in an open loop, fed with RG8; haven't tried this, but I think the SWR will be less than 2:1.

==========
A closed loop is only effective on wavelengths roughly equal or smaller
than the circumference of the loop , so a 60ft equals 18.3 metres loop
should work well on frequencies > 16 MHz or about.

For 14 MHz the loop would be best with a circumference of 21.5 metres
(70 ft) or longer ,etc

Thanks

==========
== 60 metres ,hence freq is 5 MHz ?
== Fixed frequency ?
== What is desired operating range ?
== What area is available to accommodate an antenna?

If for a limited range I would put up a single tubular (guyed) mast
with
a non-metal top end and fit an inverted V shape dipole with a suitable
length of twin feeder and a current balun/choke near the transmitter
,assuming the transmitter needs to see a 50 Ohms resistive load.
The dipole would be 2 times 15 metres long with the twin feeder length
30 meters or a multiple thereof .

Alternatively an inverted V dipole ,length 2 times 30 metres with the twin feeder length 15 metres or an odd multiple thereof.

Your question is too broad , please specify purpose and operating freq/range of the transmitter.

Frank GM0CSZ / KN6WH

That's sort of a 'broad' question. Depends a lot on where the antenna is to be situated and the state of your bank account versus your building abilities.
An antenna's environment determines much of it's electrical characteristics, so that can be an important part of the 'selecting' process. An antenna's mechanical characteristics also are part of that 'selecting' process. There are gobs of antenna 'styles'/types so those mechanical 'problems' can usually be sorted out easily, sort of.
Can't give you a particular address for that antenna, but would suggest doing lots of 'shopping' before buying. Making one to fill your need isn't unreasonable at all and can certainly be cheaper (important consideration if you're as 'cheap' as I am!).
Good luck.

> Is this concrete suitable for conduction into mother earth or should I run
> a large copper strap from the pole to an earth rod?

Hi Jerd,
The latter, and you should have more than one if possible. The strap should not have bends in it, should be low inductance (a copper strap is better than a wire, etc.). Remember there are zillions of electrons coming down that pole, and they all have to get into the earth, and all the ones in front are being pushed by the ones in back, all screaming "Hurry up, or get the hell outta the way, cause I gotta go..... real bad." And if they don't get outta the way, the ones in back will jump around them like a New York driver in a traffic jamb, to find a faster way to get where they are headed. And you don't want that to happen because the other path may be through your coax and into your house/equipment.
Now how does that portray the situation? That's the best I can do !

Should be fairly good as is. Acts as sort of a "UFER" ground.
http://search.yahoo.com/search?p=ufer+ground&fr=yfp-t-501-s&toggle=1&cop=mss&ei=UTF-8
I don't think adding another wire to ground would hurt anything,
but it's probably not needed to act as a decent lightning ground.
My mast is sitting directly into the earth. But I also run about
3 wires from the base of the mast to the ground system under
the mast, which is connected to all other grounds.
I've had two direct strikes that I know of, and they were non events.
The mast seemed to be fairly low resistance as the strikes were
very quiet. Or at least, thats one personal method I use to tell
if an object is a good lightning ground. A poor ground like a tree
will give a very loud crack as it strikes, and I'm not talking about
the sonic boom which occurs a very short time later. I'm
talking about the actual direct sound you hear from the strike,
which also gives a "click" to the auditory nerve if you are close
enough.

Like they say, a vertical taller than any other object is fair game
to lightning. Not really much you can do, except make sure
that the return to earth at the base of the mast is very well
grounded. You want it going to ground at the base of the antenna,
and not at some later point along the feedline. I would snub the
feedline to ground at the base, and run it along the ground the
rest of the way to the shack. Then at the shack, use the
usual "ground window" techniques with arresters, single
point grounding, etc..
The only thing I can think of that "might" slightly reduce the
chances of the antenna streaming would be to add a large
"ball" at the top of the whip. Along the same line as flag
poles.
And even thats no sure thing. .. :(

Hey! I heard that! <G>

I was kidding, you know.

Due to my certain lack of exposure to operating 75 meters mobile, I would
have thought that anything less than a full buck and a half of watts and
some horrendously large vertical
would have been a waste of time. I guess I have something left to learn
after all.

Problem is, outside of the R/C Flyers Net, I have no use for 75 meter phone.
Now that I'm retired, there is no reason to be mobile at 0600 these days.
I'll leave the mobile low banding for those with the need.

> Tam/WB2TT

I used 300ohn twinlead because I plan to use this as a multiband antenna and twinlead wouldn't have as much loss as coax in such a situation plus I had a big roll of it lying around. The open loop design was so I could get to a frequency as low as possible with the amount of space I had. I know I fell a few feet short on 40 meters, but it was the best I could do under the circumstances. As for the balun, I bought the switchable balun because I knew some instances might work better with 4:1, others with 1:1.

I did manage to get the SWR down a little on 40 meters by not using the balun and just connecting the twinlead with one lead to the single wire feed and one to the ground, but I had to use almost maximum inductance and one of the capacitors at max as well, but didn't work anyone.

The tuner I have was homebrewed by another ham and was built so he could load up single wire feed antennas for low band and Top Band QRP work. He told me the capacitors came out of a broadcast receiver and he found the roller inductor at a hamfest while the second inductor he made. I used it alot for tuning single wires in the past and it worked well, although I did have some problems when I went above 17 meters with RF in the shack. Perhaps it was suitable for those kind of applications, but not for this one and I may need to get a commecial tuner of figure out how to modify this one to get it to work better.

I also wonder if the feedline length could have something to do with the strange characteristics this antenna is exhibiting. It's probably 30 feet or so.

The joys of trying to get on HF in limited space.

Here are three active antennas--Do It Yourself style.

Handy on camping trips, or where stealth is desired ... anywhere you
can't use a big antenna. Sometimes these antennas are referred to as
"voltage probe antennas."

A simple pull-up antenna or short length of wire suffices for an antenna
(4-10 ft long.)

Even more off topic.. Sorry!

I have to disagree with you Mike. Depending on how you publish your email address you *may* attract machine generated email trash. My view is that it isn't worth being blase about and steps should be taken to minimize the risk. Farming of news articles is only source of such data so whatever steps one takes has to cover other possibilities.

I personally use throw away addresses that when they attract too much spam I simply change them. Many ISP's nowadays will let you have a number of addresses so it is relatively easy to maintain a set of "public" and "private" ones. At my place of work it is even easier as we run our own SMTP/25 mailserver. I generate addresses whenever someone needs to register or subscribe to something on line and dump them when their persistent advertising gets irritating to us!

I agree however with your comment about hams and privacy. The VK equivalent of the FCC also has an online database complete with full address details! I am not hard to find, just difficult to get to!

Lets face it though, obnoxious people do need to be anonymous. I certainly don't want to now them! <grin>

Cheers Bob W5/VK2YQA

> on receive.

That's correct. Common mode (unbalanced) current is induced into the feedline by the unequal radiation from the two halves of the antenna. This also occurs with an off-center fed antenna even if the feedline is perpendicular, and with coax feedline.

>

Dave you started with a simple whip 40 some inches long. As I mentioned , no mater how much amplification you have , the local and not so local noise will limit the ammount of amplification you can use. All you will amplify is noise. Lets say you have a noise floor of .3 microvolts and a signal is picked up from the antenna of .4 microvolts. Your signal will be higher than the noise and you can hear it to some extent. If the noise is .5 microvolts and you get the same signal , then you will not hear the signal. If you add an amplifier (one that has no noise of its own , which is impossiable bu the way) you may get .8 uv of signal, but you will then have 1.0 uv of noise and you will still not hear the signal. The amp may add .1 uv of noise so you then get 1.1 uv of noise and only .8 uv of signal.

You may change the antenna to a tuned loop. Take a couple of sticks about 3 feet long and make an X out of them and wrap a few turns of wire around the outside of the X so you have a loop about 3 feet square and tune it with a capacitor to the frequency you wish to hear and it will be somewhat directional. That may help.

The main thing is that a 3 foot whip in the house is not going to be a very good antenna for shortwave.

I might say "always" in place of "so often". A good reason.

> and it usually isn't the one they tell you.

Not my experience. Have you had a problem with obnoxious people not telling
you who they were? What would you do with the information once you knew the
real id of an obnoxious poster?

>And this presumed anonymity is usually accompanied by a degree of
>obnoxiousness
>
> If a person posts, they can be found.

With a court order to the ISP, yes, a REAL obnoxious poster could be found
even with dynamic addresses being assigned.

> If it is so important to a person to not be found, they should not ever
> post.

Michael, software robots do not care about the "person". They only care
about valid email id's.

> Simple. And a person interested in privacy should never ever be a ham.

That does not preclude the fact that a ham might be a "person" interested in
privacy.

>Our info is spread all over the world and open for all to see.

On the airwaves, which is a completely different medium and far less chaotic
than the internet. Some hams presume that usenet is as safe as ham radio.

Wrong. That is being naive, at least for K-W call signs.

Hi John, thanks for the reply. My coil was about what you calculated, but the vertical was of the portable variety, made from #18 as well supported by a 33' fiberglass mast. I was trying to hit 3.8 mhz, I just tried it and it was close. SWR was around 1.7 at resonance.

Since the Xl of a 37 uH coil is >650 ohms at 3.8 mhz, I had to tune the 259 to a lower F to get an L reading. When I could get an Inductance reading, it said X=0, which must mean the coil impedance must be purely resistance?? Since I have tried it and it worked OK on the antenna I guess that is what matters.

Huuuuhhhh. Okay, I think I am beginning to understand. At least, when you
put it in those terms.

I had thought about using a loop, but for some reason decided to try the
whip first. I guess 'cause that's what I had handy, and I wasn't sure how I

would mount a loop. Until I can figure that out, I am going to try tuning the output of the RF amplifier the same way I tune the input. If I can work out the last detail of doing that.

Your words, and numbers, are much appreciated. And your patience.

Thanks, Ralph.

Dave

Is it possible to communicate on a usenet group without knowing the email id of every single participant? I think so. There are plenty of anons on this ng. You say this is abhorrent, but why? As long as the discussion is about technical issues, what is the reason for your fear? Surely the truth speaks for itself and it can be verified on its own merits, independent of the email id of the author provided one has the ability to check technical references and has some background in math and the sciences, agree? What is your opinion of pen names such as Mark Twain and Lewis Carroll? Abhorrent? I don't really know who you are or care but it is frankly unsettling to think that someone thinks that I, under my my pen name, is "abhorrent"...which goes back to the reason that one becomes anonymous in the first place. You do not like me and you "could" look me up....I have no idea of where you come from but you do like to attack. How far will you go? Abhorrent.

The answer is "No".

Why?

Stand up in a clear space and spin round. It is not too difficult to turn
at one revolution each two seconds. Suppose the moon is on the horizon.
How fast is it spinning round your head? It is about 385,000 km away so the
answer is 1.21 million km/s, which is more than four times the speed of
light. It sounds ridiculous to say that the moon is going round your head
when really it is you who is turning, but according to general relativity
all co-ordinate systems are equally valid including revolving ones. So
isn't the moon going faster than the speed of light?

...And yet still the planets continue to circle the Sun on their Newtonian
predicted courses, apples still fall to the ground and rockets still fly to
the ISS.

Newtonian mechanics still rules the universe, we just have to insert the
corrections to account for space being warped a bit by the gravitational
fields of massive objects.

Stefan,

You are revolving at one revolution per two seconds. Your view point is shifting back, forward and side to side by only a few inches. Someone watching you from the moon would see your spinning around on the spot.

Your co-ordinate sytem is only varying by inches compared to the moon. You would need to be spinning a heck of a lot faster before you started to see any effects. The first would be you blacking out, followed by limbs and other extremities flying off, followed quickly by death at which point it would be all rather academic. :-)

The moon would still be there and the earth would still be revolving at 1,000 mph at the equator and therefore shifting your viewpoint faster than you ever could up to a point just short of the north or south poles.

The fact that the moon appears to be going around you at a speed faster than the speed of light is a false premise.

But relativity allows you to hold the person's coordinate system at zero
velocity relative to the moon. In the case, the moon 'turns' around the
person. Although the angular velocity remains the same, with the person at
zero velocity, the speed of the moon's 'orbit' around the person must then
be 2*pi*385000 km/2 sec which greatly exceeds the speed of light, everything

```
else excluded.
```

Hi Stefan,

It is precisely these sorts of absurdities involving zero and infinity that prompted Richard Feynman to develop new mathematical and graphical methods to describe what was going on.

If you insist on having a zero velocity then that point of rotation must be infinitesimally small and therefore has no relative motion to the moon. As soon as you enlarge this point by even the smallest dimension, then the relative movement becomes the diameter of a circle or sphere the same size. You are moving the view point around the edge of the circle, not moving the moon. I think the confusion arises because you are used to only looking in one direction at a time. From a relativistic point of view, you would see in all directions equally at the same time, from side to side and up and down. In which case, the moon would only appear to shift by the amount of circular space you needed in order to spin around.

If your idea was true, then we would be living in a universe where the maximum visual range would be constantly changing depending on our rotational velocity at the time.

The maths may appear to be correct, but you have to use the right tools for the job and in this case you appear to be using a hammer instead of a screwdriver. :-)

Try deleting the parasitic element and see what the gain of just the driven element is. The difference between this and the Yagi gain is the gain relative to a single element at the same height. This is a more meaningful measure of gain than dBi for this application.

OK, the answer: I do not think it is a particularly simple answer.

The moon is really moving at slower than the speed of light because the moon remains within the future light cone, emitted from its position, at any given instant.

Of course, the observer (one who is unfamiliar with relativity theory) may not know that unless he notices that the moon does not overtake light in its own position. Without the future/past light-cone concepts, the theory that nothing moves faster than light does not work. However, the theory is, for all practical purposes, proven. Despite that, the observer has every right to believe that the moon is travelling faster than light given what he has been taught about velocity, distance and time, if he references himself to zero.

The problem is in the old concept of "velocity"; it is not very useful where objects are purported to approach or exceed light speeds. The concept needs a fudge factor ("light cones" of past and future). As you know, the pre-Einstein concepts of linear distance and time do not apply under such conditions.

One of the contributors in this ng seems to be mixing up particles moving at or near light speed (photons) with other particles moving slower (the alleged Guassian static) model, and he is mixing up where the particles should be relative to a reference point that he sets to zero (for example, in a computer program). In respect to the future and past "light cones", the particles appear to be in "absolute elsewhere" so he thinks he has derived a new maxwellian corrollary where particle fields moving at c are generated from tank circuits. However, they simply cannot correllate fields moving at c with a summation of static particles.

30 feet is around 1/4 wavelength at 40 m. So, if the impedance at the feedpoint is less than 300 Ohms, the twin lead will transform it to a higher impedance. It will almost certainly work better if you connect the coax directly to the antenna. With or without a balun.

Art wrote:
"Let`s keep it simple. An antenna is just a pendulum with two energy storage tanks per cycle."

Not too late for a truth squad to clean up the above, I hope.

I infer from the above that Art implies an antenna to be a resonant circuit. Many are resonant because a resonant antenna has no net reactance to impede the signal.

But, there is a non-resonant class of antennas. Antennas in this class often have radiating conductors terminated at their far ends in their characteristic resistances (Ro). Traveling waves, reaching Ro which have not yet been radiated are simply absorbed. There is no reflection and no standing waves. Up to 50% of the energy fed to the antenna may be wasted but usually it is somewhat less.

50% waste is a lot, but the directive gain of a typical rhombic may be 50 times according to Fig. 23-18 on page 882 of Terman`s 1955 opus. I`ve used ountless rhombics and attest that Terman got it right.

Point is, there`s no pendulum up there, only simple wires carrying RF and they radiate like gangbusters!

Best regards, Richard Harrison, KB5WZI

Yes, I think Stephen Hawkin illustrates the time cone principle rather well in his book. As you suggest, the observer who assumes the moon is travelling, relative to himself, at faster than light speed is drawing the wrong conclusion due to an incorrect interpretation of the situation based on limited experience.

I cannot reconcile the idea of electrons or some other particle sitting on the surface of a substance just waiting to be prompted into generating a field. Clouds of electrons can exist in near vacuum conditions around the cathode of a thermionic valve, but that is a somewhat different application to a radio antenna in air. Electrons in the orbital shell of an atom can absorb and emit photons. Certain metals are more conductive than others because of the mobility of their shell electrons. Antennas made of good conductors such as copper and aluminium work rather better than those made from iron or lead for instance. Copper antennas coated with silver or gold should be even better when taking skin effect into account.

I don't know for sure, but I am pretty certain that electrons on their own form alpha particles which do not absorb or emit photons,otherwise there would be no need for a phosphor coating on cathode ray tubes. Jack the voltage high enough and the electrons would light up the glass on their own and that certainly doesn't happen, you just get x-rays.

Agree. Years ago I was an avid broadcast band (BCB) DX'er, usually getting what I wanted late at night. However, when I installed about a 50-foot dipole wrapped around the inside of my garage, I found an exciting number of distant stations available during the day. It seems old hat today, but the experience was valid, I think.

The greatest failing of modern science teaching (and don't even mention science journalism) is the fallacy that Einstein "overturned" the classical physics of Newton and Maxwell.

It is much more accurate to say that Einstein's theories wrap around classical physics, and CONFIRM its accuracy in the everyday world.

This could only be done by stepping clear outside of classical physics, and Einstein is rightly famous for that huge advance in human understanding. But it wasn't just a wild leap of conjecture. He could only do it by understanding classical physics better than any human before him.

But Einstein's equations of motion showed that, at everyday sub-light speeds where the relativistic term (v/c)^2 tends toward zero, those extended equations simplify right back to Newton's laws of motion; which therefore stand confirmed in our everyday world. Einstein's contribution was to allow us to calculate the error involved, and to confirm how tiny it is.

The same applies to Maxwell's equations: for the everyday world of antenna engineering, these too have been confirmed by Einstein.

Ah, but "overturned" feels so much more comfortable! It makes such a soft excuse for failing to get to grips with hard physics. Einstein would be appalled.

Oh, I understand that a larger antenna is much more receptive. And I have a
110' random wire that does wonders. I am just wanting some sort of
reception booster to take with me if we have to bug out for a hurricane
again. That, and the challange interests me.

I get huge amounts of spam at this address, but it is because it has the dread initial/number/domain combo, not because I post to newsgroups with my real name. The spammers simply send out mail with a gazillion combinations of initials/numbers/domains, and hope something hits.

In my other address, I post with real address and name too, and get very little spam.

I wonder just how much newsgroup harvesting is doen these days. It wouldn't be very efficient.

The moon is in the motion path that it is in, and your personal
rotation, while it might make you dizzy in the end, is merely local
changes, not one of which can exceed the speed of light.

Another example might be two particles which accelerate away from each
other at or near the speed of light. While if it could be measured, it
might appear to observers on each particle that the other one is

breaking the galactic speed limit, each is conforming quite nicely.

Here is a link that might help

> field.

Hard to reconcile if the thought stands alone, but it doesn't
Foe the first time it has been acknoweledged that Gaussian field
are directly implicated with radisaon.(All agree that the method
I proffered where a time varient addition
is the same as Maxwells law
Free static electrons must rest on something and only a
few substances allow that. Thus if such items are pla`ced in a
Gaussian
fiedl where they do not upset the equilibrium of that in the field
one
can deduce that in fact they are sitting on the surface. For an
addition
to maintain the equilibrium it must be a wavelength long.

Now you move along and view what happens with respect to the Gaussian
aproach
ie flux analysis and how they remove themselves from the arbitary
Gaussian field

Ok, I did. The gain at 7 MHz went from 11.2 to 7.22 dbi, at 30 degrees
elevation angle.

Hi Art

I thought you might comment. I am about to start (re)reading through the works of Kraus and Terman to check on any gaps in my knowledge. As I understand physics at present, photons are the 'carriers' of electromagnetic fields and electrons per se do not propagate electromagnetic energy in themselves. An electron may be liberated from the orbital shell of an atom and accelerated into a target to produce x-rays or lower energy emissions, but those emissions only arise after the electron has recombined with an atom and balanced the excess energy by emitting a photon. Electrons can not exist in isolation for any plausible period of time under normal atmospheric pressures because they almost instantaneously end up colliding with an air molecule as soon as they are liberated. Your ideas might have some possibility of working in a hard vacuum environment but I doubt they can be achieved in air, there are simply too many other particles whizzing around and colliding with things. A look through a microscope at some pollen grains suspended in liquid will show Brownian motion. The pollen grains which are quite massive compared to the size of an atom, are buffeted all over the place by collisions with molecules. I appreciate that liquids are denser than air but I fear the same thing must happen to your static particles.

Priz wrote:
"I`m working with attic antennas and need some help."

The attic is a poor place for antennas but a good place to experiment.

A 60-ft. perimeter is over one wavelength at 15 meters.

According to Arnold B. Bailey`s "TV and Other Receiving Antennas" Fig. 8-14 on page 408, an open-circuit large loop has a radiation resistance of less than 80 ohms. A closed-circuit large loop has a radiation resistance of over 40 ohms.

A closed-loop`s radiation resistance varies less with frequency than does the open loop.

Borrow the book. Look at the chart. Pick the radiation resistance you want and proceed.

Best regards, Richard Harrison, KB5WZI

In doing some study of active receiving antennas I see in a couple of white papers on the subject that the author determined he needed a specific phase shift between one or more of the elements and the combiner, such as 110 degrees, so he proceeded to cut a specific length of coax determined by it's velocity factor X the desired fraction of a wave...
This is one of those things that you always accept at face value in a published work, but this time my doubting side kicked in... We know that simply inserting a nominal electrical length of coax - such as 90 deg or 180 deg - into phased transmit arrays does not work as planned most of the time due to mutual coupling... I have read the contributions of Roy and Al Christman, et. al. on this <not intimating that I understand it>...
Anyway, in shortened, loaded, active amplifier, receiving arrays can one simply insert a nominal number of electrical degrees of phasing line as the mathematical model calls for, or is their more to it...
Hoping that Roy, AL, or Walt, or others will chime in here...

Well Mike you must be close to my age group if you are using an
analytical aproach
instead of the modern aproach of taking a poll.
First we will examine what we have and not resort to Newton in any
way
since this is a electrical problem ala LLewallen. We also must not
rule out
anything that is unlikely ala Woods of the Naval academey.
We have two materials aluminum and stataic particles of a material
unknown.
You correctly raise the point of collision which if they are a means
of
communication that must be able to travel in a sort of straight line.
In electrical terms I suppose for a collision to occur the subjects at
hand must be
polar i.e to attract or repel. Soooooo we look at aluminum first and
we see that
it cannot retain magnetic properties i.e it does not retain a typical
hysteresis curve
which designates magnetic energy or polar presence. Now static
electrons. We know they
have very little energy right from the beginning and are not affected
repelled or attracted
by magnetic fields such that we know its velocity if given is not
affected by
polar objects that may cross its path. We also know that aluminum is
one of the
very few types of material that will allow the chemical adherence of a
static
particle to it's surface without it being collected into orbit around
the
resident atom.
With the above in mind it would appear very logical
for a static particle bound in a Gaussian arbitary fiels where all is
in equilibrium
for that partical to be at rest on the only thing possible within the
arbitary field
which is a aluminum radiator of a particular wavelength. Since we are
dealing
with scientific analysis and not the number of voted for or against
we must first
come to agreement with the logic profferred as opposed to what is
unlikely
and review the hypothesis for any violation of electrical, not
mechanical,rules.
My best regards
Art Unwin KB9MZ...XG

Roy has a SIMPFEED program available from eznec.com that
will tell one if what one is trying to do is possible
and then perform the calculations. I tried the early
version on phased verticals on 75m in AZ and it worked
very well. I could throw a coaxial switch and switch the
beaming function toward CA or TX.

Also, using EZNEC to estimate the feedpoint impedances,
one can always use a Smith Chart to solve the feedline
phasing problems the old-fashioned way. (Years ago, while
using Microsmith, I stumbled upon a method of obtaining
a free lossless phase shift.)

It would still not exceed the speed of light. No laws are violated by
objects moving at speeds that when summed are moving faster than light.

It's kind of like two cars that are each traveling 60 miles per hour
toward each other. They are approaching each other at 120 miles per -
assuming they are traveling straight towards each other, but they are
still going 60 each.

Okay so far as it goes Art, but I have a problem with an unknown, essentially neutral particle existing on the surface of the Aluminum. You state that the static prticle is neither an electron nor a photon, so it must be something else. Perhaps this phenomenon is related in operation to the suggestion for a plasma antenna mentioned in a new newsgroup subject thread. I can see how that would work. I always use an analytical approach to any problem. It's paid my wages for the last 30 years!

Regards
Mike G0ULI

> coaxial cables,

Ian, I have no disagreement to your reply above other than you are
being to king in your response
I personaly would have put more emphasis on what you stated with
respect
to RF traveling along a path that has no external surface .With
emphasising
where many have about RF travel without which one CANNOT understand
coaxial cables or braid The inside of braid on a coax CAN and DOES
carry
RF current but it does NOT radiate, because it does NOT have an
exposed surface
other than a dielectric interface. The outside surface can and DOES
radiate if a
RF current flows on the outside of the braid. I would also add that
copper/braid
itself does not turn into a dielectric or contain a diode thus it
also WILL
also pass a RF current at its centre but of course does NOT radiate.
This very fact was refuted by popular vote on this newsgroup where
poll
standings always overule science. So yes, without true understandings
errors
are sure to congregate and eventually will create a "fact".

OK, well I have had EL and EZ from the early days to the current Eznec + v5 and I use it often.. (about as well as a cow tap dances)

And I have read the stuff I mentioned - and in particular, Tom submits that a shortened, heavily top hatted, heavily R loaded, 20 foot vertical element on 160, is free of major impedence shifts in the presence of other objects/ antennas... So, one is free to infer that perhaps one could simply insert a calculated length of coax between two array elements to get a desired phase shift without calculating for mutual coupling?

The impetus for this line of thought is this morning I was having problems working VK land on 160 as the DX was only about Q3 at best moments and Q0 at others... So, not hearing well I hesitated at the critical moment of turn over and W1MK stomped on me...
I have a 4 Square active receive array but that lobe favors JA over VK and I don't have a Beverage pointed in VK direction having gotten rid of most of them after getting the active array...
Anyway, I am tinkering with a 4el endfire-broadside <70 x 270 spacing > receive array and the best pattern is with 135 degree phase shift between the endfire elements - which is what prompted my question as I know that if they were full size transmitting elements I cannot blithely just insert a calculated 135 E degrees of coax and get the wanted phasing...

Looks like I will have to put up a pair and custom engineer the phasing line...

I said that in deference to those who have assigned names in the
electrical
field who get irate withg respect to nomenclature. I am happy to call
or
describe it static particle to stop side tracking from the essentials
of this debate

So you now say it is OK as far as it goes.
The nexr step is to add a time varient to this Gaussian extension
to allow continuance in radiation as seen by Maxwell.
We examine the electrical circuit that is shown by the material inside
the arbitary field and we can derive a electrical circuit that has
a inducrance, a capacitance and a resistance in parallel which
constitutes
a resonant full wave length aluminum radiator. We also have
sitting/resting on the aluminum or any diagmatic material a particle
whish is static and possibly unnamed. We also can say that Kraus has
determined not by mathematical reasons but empirical methods that the
radiation is not on the same axis as the radiator. By his use of a
helix
we can also say that a helix is in equilibrium and thus can be of any
shape.
The biggy is that mathematics for this scenario must meet Maxwells
laws.
We can now us computor programs that are based solely on
axwell's laws. First we start recording what we know. The radiator
must
be at an angle with respect to earth per Krauss's findings.
Now we let the program optimizer determine if this conforms to Mawells

laws.
But one more thing. When we drew the electrical circuit what came abot
was
a "tank Circuit" where it is implicite that both the capacitance and
the inductance
expell their retained energy in sequence and at a rate acording to a
time constant
disregarding overshoots. This time constant is on of varying energy
release
per unit of time, a factor that must be present for radiation.
So we have an optimizer that we can insert a radiator of onw wave
length and at any
angle with respect to ground and allow it to correct the input to that
which meets
Maxwells laww for say max horizontal radiation. Doing this we must
expect a
radiator that is resonant, at an angle that differs from the plain of
the earth
and more importantly, more horizontal gai that any other full
waveradiator can supply
regardless of its orientation.

Sooooooiooo get iout an optimizer. Insert a radiator at any angle.
Review the results to see if that demanded by a gaussian extension
is verified by using a computor progam optimiser that is based solely
on Maxwells laws.
Comment please or procede as requested in search of the truth.
My best regards
Art Unwin.....KB9MZ.....xg

Good for you but it is viewed as old fachioned on this newsgroup.
Yes, it is well known that a neon light and others are able to recieve
R.F
and react by emitting a light wave. Because of reprocity truths it
must
therefore be able to radiate. But we diverge from the case at hand.
We are studying the scenaria that a Gaussian extension shows with
respect
to that enclosed within a arbitary border. Straying from that basic
stance
de legitamises any connect to radiation expouse by Maxwells laws.

Hi Mike

Well if I was creating a databases of addresses to SPAM (shudder!) I would add on an SMTP engine that tries to connect to the host. If I got a "550 mailbox not found" or something similar I wouldn't ever bother trying again. It would be fairly easy then to have a known vs invalid addresses. That along with (say) grabbing names from telephone books and creating addresses with it for every domain that could be found would build up a credible database to work with. Once the engine is perfected a 95% failure rate is still a success..

I am sure there are institutions around that do this, if just to sell a useful database to their customers. There are however far better and more slimy programmers around than me!

I would suspect (but don't know) that ISP SPAM mitigation processes are helping a lot nowadays. There have also been laws passed and ISP acceptable use policies that are making things a little bit harder for the SPAM creators... Most mail servers also have a lot of lookup/checks that go on nowadays when they receive a connection. I think about half at the place I work fail to connect because they are requesting relay, have an invalid source domain/reverse lookup or something else that prevents the chaff getting through. Those that do then have the SPAM pattern filter trounce about 95% of.

Cheers Bob VK2YQA

Okay, tuning the output along with the input does help, but it's still very close to what the built in whip on the 7600GR does. The only real difference between now and before is less noise, which makes the intelligence more accessible (easier to understand what they're saying.) Time to try the loop, for directional input. I still wonder if something I thought about a while back might work, which is to mount a second whip on the other side of the case and seperate them with coax internally. I had some numbers in mind at one time, but have forgotten them. Roy Lewellan suggested I try EZNec, but I haven't been able to dedicate as much time to it as I thought I would. And someone I met is mailing me a copy of the CD from the latest ARRL Antenna Handbook. It is my understanding that phased verticles have been completely re-addressed in this latest copy, which interests me. For some reason books, even on the computer, speak to me more easily than applications for modeling given situations. Going to go try EZNec again.

One thing I realized, to my own benefit. The house has steel siding, and that degrades the performance of the 'whipped' RF amplifier considerably. Outside, in the driveway, it works as well as it does inside, off of the external 110' random wire. Which is a better performance by at least a factor of 10 when compared to inside, off of the whip. I'm going to keep squeezing this lemon. One way or another. It keeps improving by considerable steps, I just have to work the bugs out.

Thanks all, for ideas and feedback. And patience.

Dave

That's the gain of an NBS Yagi in free space. It's more like 13 or so over ground, depending on height and ground characteristics. Comparing the gain of one antenna over ground to another (for example a dipole) in free space is a trick often used by antenna manufacturers to fool naive people. Both must be in the same environment for a comparison to be meaningful.

I'm glad my harping on this topic (mostly via Chapter 8 in the _ARRL Antenna Book_) is having an effect, and that some folks are catching on.

The receiving antenna trick is to begin with elements that are either very short or very lossy or both. This reduces the effect of mutual coupling to a negligible value, so all elements will have the same source impedance. Then the transmission lines are all terminated in their characteristic impedances at the receiver end. This is the condition under which the delay in the lines equals their electrical lengths. Under those conditions, the scheme works nicely.

Roy Lewallen, W7EL

Hmm, so by optimising the angle of the resonant radiator with respect to
earth, you control the beam width and take off angle and thus the effective
gain. The resonant element does not have to be linear, it can be in the form
of a helix which allows for the antenna to be of compact dimensions. The
secret being the precise angle at which the helix is wound and the optimum

angle to orientate the wound, resonant, radiating element with respect to earth in order to achieve the effective gain figure required. I can accept that a system like that could work. I think that it is capable of being described using standard physics. Certainly a working model would allow measurements to be made to confirm that this was so, or identify any departure from the currently accepted antenna theories as you insist it does.

I await developments with interest.

Best regards

By Golly. Well done. You should get a gold medal from your peers
namely George W Bush.
You and you alone was the first to point this out to the scientific
community.
You take credit for harping on it in a published book knowing if it is

in
a book it then qualifies as being right.
What ever did the radio community do in those
case before you were born or came along? You should undoubtedly get a
medal for harping in leau of saying "I don't understand" or you
can't
use mechanical laws when the subject is electricity" plus some of
those things you have stated that Cecil could remind you of.
Yes, the credit is yours and you get the gold medal and a fireside
chat with your equal and possibly a mentor George WWWWWWWW BUSH.
YEA....

> that he is stationary?

An observer simply defines himself as stationary. Of course, nothing stops you from doing that. As an electrical analogue to this mechanical situation, I can define 120V as ground relative to real ground and the calculations will still work within an isolated system. The problem is that the real universe does not allow anyone to define themselves at zero velocity in all coordinate systems. When relativistic speeds (IN THE FORM OF VERY LARGE DISTANCES in small time intervals) are involved, the concept of velocity (d_/dt) seems to blurr to the point that zero velocity is meaningless. However, it is very meaningful when slow speeds (short distances/reasonably large delta t's) are involved. At relativistic speeds you need the future/past time-cone model to supplant the explanation of events at low velocity. So, either "velocity" is a meaningless term when v => c or future/past time cone theory is a fudge factor to explain observed effects at velocities approaching (or allegedly exceeding) c. I'm not sure which it is yet. However, it is not a simple answer to what seems to be a simple question. It is almost a paradox & it is discussed in the literature. If nothing else, it shows that particles need not be located where the standard concepts of velocity/time/distance would predict them to be when causing maxwellian time dependent fields. A certain contributor to this ng (I mention no names) would likely disagree. Time cones are not parallel; thus an electron that an observer thinks is completely independent of the fields it created may exist in "elsewhere", outside the time-cone. Thus it is not useful to use a Guassian static concept to try to explain EM waves...it simply cannot be observed or conceptualized.

Cecil,

That's the whole point of relativity. It doesn't matter if an observer is stationary or in motion. All movement is relative to everything else. A weightless astronaut locked in a heavy light proof box would be incapable of determining whether he was in orbit or in a vertical free fall towards the earth. There is no outside reference to make a judgement. Similarly, an observer at any point in the universe can consider themselves to be stationary with respect to everything else because there is no other point of reference. Each observer will determine the speed of light to be 300,000 Km per second within their own frame of reference. A god like being outside of the system would be able to determine that different time rates applied to each of the observers thus ensuring that they all measured the speed of light identically. It's all relative, you see?

Mike G0ULI

I don't remember mentioning about control of beam width and take off
angle
Please point out where so I can review.
A radiator can be any shape or configuration resonant element as long
as it in equilibrium
is how I define a radiator without going into the material that it
must be made of.
If you can remember where I gave a definition that opposes that then
please
let me know so I can review it in context.
Many times I have been accused of saying something when it is the
accuser is misreading or stating
something I said in a different context. This is not unusual in news
group conversations
to side track the subject tomake room for another.
Have you or anybody used the/any optimizer to check things out? It
would be usefull to see the results
and put them in passive programs such as EZNEC which cannot optomize
but can
give you radiation results from pre designed radiator based on
Maxwell's ,laws
When this is resolved we can then move on to arrays derived from the
Gaussian extension and compare that with other std NEC 4 programs. But
I would like to resolve the optimizer question before we progress
further
so that you have the opportunity to raise questions.
After all, we are doing a scientific analysis here that is not subject
to over rule
by a poll result of the members who go by the golden rule that every
thing is already known!
Best regards
Art Unwin....KB9MZ.....xg

I don't remember mentioning about control of beam width and take off
angle
Please point out where so I can review.
A radiator can be any shape or configuration resonant element as long
as it in equilibrium
is how I define a radiator without going into the material that it
must be made of.
If you can remember where I gave a definition that opposes that then
please
let me know so I can review it in context.
Many times I have been accused of saying something when it is the
accuser is misreading or stating
something I said in a different context. This is not unusual in news
group conversations
to side track the subject tomake room for another.
Have you or anybody used the/any optimizer to check things out? It
would be usefull to see the results
and put them in passive programs such as EZNEC which cannot optomize
but can
give you radiation results from pre designed radiator based on
Maxwell's ,laws
When this is resolved we can then move on to arrays derived from the
Gaussian extension and compare that with other std NEC 4 programs. But
I would like to resolve the optimizer question before we progress
further
so that you have the opportunity to raise questions.
After all, we are doing a scientific analysis here that is not subject
to over rule

by a poll result of the members who go by the golden rule that every thing is already known!
Best regards
Art Unwin....KB9MZ.....xg

Hi Art,

No you didn't mention beam widths or take off angles. However since gain is measured against a theoretical isotropic radiator or dipole suspended in free space, then the only way to achieve gain is by distorting the spherical wave front. So inherent in your gain prediction, the wave pattern must be distorted from a sphere (or hemisphere close to the ground) and optimised for a particular direction and/or take off angle to provide horizontal gain.

What you did appear to say was that by using your design and adjusting the angle of the resonant element with respect to earth, horizontal gain superior to other antennas may be achieved. You did also say that the helix could be of any shape too.

Direct quote from above...
"So we have an optimizer that we can insert a radiator of onw wave length and at any angle with respect to ground and allow it to correct the input to that which meets Maxwells laww for say max horizontal radiation. Doing this we must expect a radiator that is resonant, at an angle that differs from the plain of the earth and more importantly, more horizontal gai that any other full waveradiator can supply regardless of its orientation."

No argument from me.

As I said earlier, the only sure way that this will ever get proved is when a working model gets built and tested. Measurements can then be made in the old fashioned empirical way a la Terman et al. That is the only way you will ever manage to convince anyone on this newsgroup Art. Computer modelling is all very well, but you cannot model a new physical process that has not been built into the program. History is full of tales of people being told it will never work, but they persisted anyway. When your design successful, you to will be able to tell everyone, "I told you so".

I don't use computer modelling programs for antennas since I tend to stick with basic designs that require nothing more than back of an envelope calculations. So I am not really in a position to confirm your results using NEC.

Regards
Mike G0ULI

I missed the part where he said it was modeled 23 m over ground..
But then you have to wonder about the ground quality used.
Thats why I always quote antenna gain using free space numbers..
I often forget that some people don't always do this... :-/
Gives a level playing field that works for anyone no matter where they
are.
I never quote gain numbers including ground effects unless I
specifically
mention it due to some reason. And thats very rare. So I tend to
constantly
think in terms of free space gain most of the time if I'm thinking or
talking
about antennas not mounted in any specific location.
One can always add the effects of ground themselves if they desire
that
for their local QTH.

This isn't quite true.

A large fraction of the amateur population think only of Yagis when they think of antennas, and often assume that whatever is true for Yagis is true for all other antennas. It isn't.

Consider two horizontal antennas, such as a dipole and Yagi, modeled (or constructed) in free space and at some height over ground. The free space gain difference will be the same as the over-ground gain difference only if the two have the same elevation pattern. Otherwise, different fractions of the total field will reflect from the ground at various angles, resulting in a different over-ground gain than free-space gain. So knowing the free space gain doesn't necessarily tell you what the gain difference will be when mounted over the ground.

As it turns out, both dipoles and moderate sized Yagis have broad elevation patterns. As a consequence, the free space and over-ground gain difference is about the same. So if you know one you know, pretty closely, the other. And people often assume this is generally true for all antenna types. But it isn't. A W8JK type array, for example, has a decidedly narrower elevation pattern than a single dipole, so the over-ground gain difference between the two isn't the same as the free space gain difference. Worse yet, the maximum gain occurs at a different elevation angle, so even if you point both a W8JK and dipole or W8JK and Yagi in the direction of the same distant station, you might not see the

predicted gain difference because of the different elevation patterns.

Another problem arises when comparing antennas with different polarizations. Vertically polarized waves are affected by ground reflection quite differently than horizontally polarized waves. And the nature of the ground reflection of vertically polarized waves is affected much more by the quality of ground than horizontally polarized waves. So the difference between horizontally and vertically polarized antennas depends heavily not only on whether ground is present, but also its quality and the heights of the antennas.

Not all antennas can be rotated like Yagis, either. The dB gain of an extended double Zepp (EDZ) compared to a dipole is negative in most directions, so that's what a user would experience when using one for general communications. Yet you universally see the dB gain of an EDZ with respect to a dipole quoted as a positive value. The moral of that story is that when comparing antennas you can't rotate, a single value for gain isn't adequate to describe the difference. You need to know the gain in each direction for a meaningful comparison. (That's why antenna modeling programs give you a polar plot of gain and not just a single number.) And even if you can turn the antenna, you'll need multiple gain values if the antennas have different elevation patterns.

When modeling -- or measuring -- antennas, if you want to know the gain of an antenna compared to a dipole, say, the only way to reliably determine it is to model -- or build and measure -- both and compare the two. In the direction(s) of interest.

Roy Lewallen, W7EL

Where do you get off criticizing Art, when it was you who has
been saying that a time variant could not be added to Gauss's law.
It is Art who has been proved to be right, and you and others on
this group who have been proved to be wrong.

Is it possible Art could be right in the rest of his thinking?.

I am sorry the way I responded because all my computor showed was a
few lines. I now see
that the newsgroup computor has gone awry. I have now read the full

text and I have
been taken by surprise. I never thought the occasion would come along
where somebody was capable of individual thought AND to be a member of
this newsgroup where hams follow the path of lemings
or those that jeered at Madame Guillotine arrangements for collection
of heads.
Yes I am aware that this will take a long while to be excepted by the
ham community as well as those
who search for monetary rewards as being part of the hobby.
Ofcourse I have made samples that confirm all the above but no way am
I going to share it with the ham community after all the abuse I have
had to suffer from this newsgroup. Hams are not interested in the idea
of new antenna design or experimentation. Go to any hamfest and
observe what the ham population appears to be.Just for the fun of it I
would like to continue with the analytical study where somebodyplaces
a design of their own on a optimiser and share it. Then all hams can
visit the EZNEC site and confirm the results for free. Only then can
we continue on the analysis since there is so much new that becomes
revealed.
gain, thank you for your kind words and the personal scientific
analysis you have shown a willingness to share.
Best regards
Art Unwin...KB9MZ and of course..... born in the East end of London
where it is obvious that the residents can't possdibly be educated
after the luftwaffe removed their senses.
Same goes here in America when you hear the accent of a black man!

Don't feel bad. My sister-in-law still spells it like you did, and I've been married to her sister for 39 years. Many years ago, I idly collected misspellings from mail, memos, and the like, and had accumulated more than 30 different ones when I lost interest.

One way is just as good as another, anyway. My particular spelling came from the first literate person in my branch of the family who, in about 1850, spelled it like it sounded to him. His brother, and many other relatives as they each became literate, spelled it in various other ways. Including, I'm sure, the way you did. Considering the family's history, it wouldn't surprise me if there are still a few branches yet to become literate and devise their own spellings.

Roy's surname is of Welsh origin. Queen Bodacia and her sisters
prevented
Romans who had conquered England in the BC era from conquering Wales.
There is a statue of that defiant queen on the side of the River
Thames
opposite the House of Commons and the House of Lords(and Big Ben).
Roy does not spell his name as in the traditional Welsh language.
Probably those on Ellis Island misspelled it not understanding the
lilting
accent of a Welsh miner.

Well said, Ian.

I'm reminded of a mental image attributed to Richard Feynman. He
commented that discovering how the universe works is like watching a
board game to learn the rules of the game. Imagine learning to play
chess only by watching the moves the players make. But then realize
that for this game, you can only see a small part of the whole board,
and there may be moves going on you can't see. Maxwell and friends,
Newton and friends, transcribed rules that seemed appropriate to the
amount of the board they could watch, and did a darned good job of
it. But since then, we've been able to see more of the board, watch

more moves, and we've AMENDED the rules that those wise and observant people wrote down, to align with the game as we're now seeing it. I fully expect that the rules will continue to be amended, and indeed we may never know for certain we've seen enough of the game to be able to write all the rules down with absolute accuracy. But I also expect that for those of us who play only the part of the board that Newton and Maxwell observed, the rules as they saw them will serve us well. We will continue to build houses, skyscrapers, bridges -- all based on Newton's rules, without any need to resort to the amendments. We will use transistors and resistors and capacitors while seldom thinking about the quantum and statistical effects that are important in how they perform; everything obeys the full set of rules that nobody yet knows, and I think it's very nice indeed that we're continuing to expand our understanding of the rules, but it's quite possible to play a very good game indeed without having to resort to all of them, all the time. Conversely, it's important to understand when it IS important to consider the expanded set, and to ever keep our eyes open to situations not adequately covered by the best set we currently understand.

Cheers,
Tom

If Gauss's law regarding the behaviour of charge over a given surface was
true 1 second ago, then same rule applies right now and it will also apply
one second from now. Over a whole span of time, Gauss's law was met.That is
obvious and needs no proof.

Hmm..
The discussion was stopped in its tracks many moons ago when this
newsgroup
before you arrived were adamant that you could not add a time varient
to
a static law A Doctor from MIT who also is a ham came along with the
proof
that you presented the other day. When you stated that you could go
along
with his math was when everybody jumped on the bandwaggon. The
archives
show that Dr Davis's mathematics which is my extension Of Gaussian law
was legitamate even tho until the other day did any body voiced
acceptance
of the math side. Yes. It came out the same that the masters deduced
but
did not explain why. Thus the puzzle or mystery sought by scientists
for decades.
What we have is a jigsaw puzzle made by Maxwell where users only had
the musings

or deduction of the masters but with out the accompanying
information.
If only Maxwell had used an extension of the Gaussian equation which
at that
time was not part of electricity but just a subset. Any how the
extension
was never brought into the picture. Now we have an extension that was
not available till now. Kraus can now smile at the corroberative
information
that he observed and documented without being aware of its origins.
So what you say! These new guidelines changes the idea of a sino
soidal curve being present
at EVERY segment chosen by computor programers, a result of an
illegitamate addition
to existing law. So what you say! Now we can design antennas with more
gain in required areas
than we could before. So what you say! Art has an antenna for the top
band that is directional and rotatable on the top of his tower. So
what you say! Smaller arrays can be made with the same radiation
capabilities of the larger yagi which by the way is narrow banded. So
what you say! Now antennas of the stack variety can now be made with a
single feed.
So what you say! Now a broadcast band antenna can be made where others
have failed ala cross field antenna.
So what you flippantly say, which allows you to be a part of the
baying crowd. Well for me I do care
what creates radiation as many others do and look forward to other
people picking up the trail where nobody has walked before and to be
around when the new vista is shared with the human race.
History shows that acceptance will not come while I am alive. But
being part of the evolution is enough for me. For the younger set they
can have the honour of saying it was all obvious and needed no proof
because I knew it all along. How? Well because., Just because.... Its
so obvious to everybody.......
It needs no proof.
So what indeed !
Art Unwin KB9MZ....XG.(Meaning an Englishman)

I can say well said to you also.
Your views elucedated here are not seen by the majority
who follow in the same footsteps of their teachers.
Even today we hear of people walking away from the common track
and even piercing the deepest thicket with great effort and
then to behold a vista that the throngs who followed the well
trodden path had passed by for centuries.
In California hikers have found an ancient indian community
remains by not following the normal trodden path.
A few weeks ago an ancient site in P.R.where people lived at the
turn of the century.Zero zero AD ...no less, again for moving
away from a well trodden path for the first time in 20 centuries!
Many people these days do not read a newspaper, content
to live happily without knoweledge of what goes on around them.
Snickers upset me not as I am content and happy with what life
has given me.
Best regards
Art

> So what indeed !

Doesn't the fact that Gauss's law is expressed without a time variant
suggest that the law IS independent of time, thus it should hold true on any
segment of the antenna system regardless of time? I assume that the EZNEC
program would not contradict this. Davis did not contradict this. I'm sure
that the maxwell people assumed it to be true as well since they included
all 4 equations of both time variant and static derivations all in the same
bundle. I think the bottom line is that what you discovered, the 'great'
mathematicians already assumed. You know, that is why they call these
"laws"; They hold true over variations of time. For example, if I drop a

coin on the floor today, I expect it to fall with a certain force = ma. If I do it one second later with a large coin, I would expect the same gravitational law to hold true although the mass of the coin, thus the force, has changed. Davis' example looked at a certain area and confirmed that 'yes the charge behaves according to Gauss' at the point in time he 'observed' it and sort of mentioned it as a "by the way" because he was able to show you he observed it. I don't think anyone was calling this a great discovery. This is not adding a time variant to a law, it is in fact say that there is no time variant, i.e. the law stays the same with time. And stop trying to relate EM fields that travel at the speed of light with static field in line segments; although analyzing such fields with reference to a snapshot in time of an accumulation of charges will verify Gauss's law, this does not mean that Gauss's law can have any relavance to the time varible field that caused them to be there. Gauss's law is merely an observation, nothing more. No likelyhood of further development when time dependent variables such as distance and velocity of the waves are attempted tio be put into play. As the EM wave is at relativistic speed, there is no hope of relating the position of the wave or waveshape or phase to a static particle unless the static particle moved at light speed which it can't and won't.

That's it. I can say no more. I think I will onfusing myself if I continue. It is a big 'so what'.

At the beginning, Einstein did allow us to assume to be at zero relative to other coordinates. But newer knowledge may add corrollaries to such assumptions (which were not taken that seriously anyway) stating that actually 'exisiting' in a zero velocity system is not possible in this universe'. I think Einstein originally thought of the universe was static (zero) where forces balanced. Later on he accepted some expansion but still used the possibility of zero reference points largely to help explain his theories.

And I agree that, if that were true, at or near relativistic v we would draw those false conclusions (if we did not know we were in those conditions and thought we were really at zero).

I was going to say that I think that Hubbel observations have hypothesized where we think we are in terms of uninverse expansion velocity because I read that somewhere, or so I think I did. One might say that Hubbel research is opening up exactly the possibilities you mention and I would not attempt to disagree. If so, the great news would be we 'know' it and we can readjust our calculations. It is interesting however. One can dig as deep as one is able (or want) to comprehend intellectually. One might even make a new discovery; (Editor's note: Not referencing anything about the Gauss Static law here). I am an old man but especially for young, new discoveries may be ripe for the picking.

Art wrote:
"Why do the scientists still refer to the emperical instead of using Maxwell`s laws to determine them?"

The proof of the pudding is in the eating. Calculations symbolize erformance. Measurements can be factual.

Kraus invented the axial mode helical antenna after an expert predicted such an antenna could not work. Kraus immediately went home, wound some wire around a form, hooked it to a generator and it was an instant success. Analysis quickly followed his discovery. Kraus and his associates produced all the math needed to make similar antennas. My 1950 edition of "Antennas" is rich with formulas and tables. With the labs available at The Ohio State University and the expert though inexpensive labor at hand to work on the new discovery, I`d bet my last dollar they got the numbers and the formulas right.

The commercial helical antennas I`ve used in the 450 MHz band compared favorably with the corner reflector antennas we also used in that band.

Best regards, Richard Harrison, KB5WZI

small problem, at relativist velocities (such as those near the speed of
light, classical laws of motion (and euclidian mechanics) break down.

we are not talking about low velocity here, we are talking about effects at
or near the speed of light. Given that Einstein realized that his laws
acted as a wrapper for higher order math around the simple laws that were
proposed by both maxwell and newton is beside the point.

Now, I have been too many years away from the math and the design aspects of
antennas, but I do know this, what we have observed so far about "antenna
theory" is pretty much correct. those are facts that cannot be disputed.

now, how an antenna couples the energy into the local space is a bit more
technical than I have working knowledge of. I just know how to build them
and how to use them. thats it.

---

art, you really need to buy and read Terman's RADIO ENGINEERS' HANDBOOK or similar source, instead of relying on your intuition. Terman provides the following equation for the r-f attenuation of air-insulated, copper coaxial transmission line:

a = 0.00362 SQRT(f)*(1+ D/d) / D*log(D/d) dB per 1,000 feet

where f = frequency in MHz, D = inner diameter of outer conductor, d = outer diameter of inner conductor.

Note that the attenuation is the same whether the inner conductor is solid or tubular. This is the result of "skin effect," which for r-f frequencies 1.8 MHz and higher confines the r-f current on the inner conductor from its outer surface to a depth of less than 0.18 mm.

The observer doesn't prove that he is. There really isn't a stationary reference point in the universe. Everything is moving. That's a big part of relativity.

While still possible - that is not very likely. Hyper-inflation would not have been or be a pleasant time to be a life form (obligitory "as we know it" inserted)

Defining the earth as stationary
> would lead to false conclusions like things are getting
> farther and farther apart faster and faster when it is
> only a relativistic effect masked by our false stationary
> assumption.

We can see that we are moving away from some objects, and toward some others. So the evidence fits very well with a three dimensional universe. The doppler red and blue shifts are consistent with nearby stars that we can measure parallax and compare their own red/blue shifts.

Is there another possibility for the extreme redshift of presumably faraway galaxies? Sure. Light could be slowing down, or even variable in speed. But I really doubt it. Seems like the sort of thing made up to fit conditions to a preconceived notion rather than explain how things are. Variable light speed is more at home in the creationist toolkit than serious science. If light does indeed slow with time, we should be able to measure it with present day light, with present day tools.

All hell breaking loose? There wouldn't be much to see until after 3 minutes or so. Then photos popping into existence. It would be plenty hot also.

I'd not assume that the Big Bang was a stationary event, so we're still int relativity. And I suppose this is heresy, but I'll become a full believer in the Big Bang once we see a proton decay.

Assuming the amplifier has an output impedance that matches that of the transmission line (75 ohms might be convenient in this application.. inexpensive low loss cable tv coax), you're right. Just lash that coax in there.

Don't forget you also have to deal with loss/amplitude.

Or, as the OP mentioned, if you have an *active* array, with buffer amplifiers at the elements, the amplifier provides the needed impedance characteristics.

One should be aware that this formula applies only to "large" coaxial transmission lines, where the skin depth is a small fraction of the conductor thickness.

It's not like the current is confined in a uniform band of the skin depth, and zero elsewhere. The skin depth is a convenient mathematical fiction.. it's the depth at which the current density is 1/e, so you can calculate things like voltage drop by assuming a uniform current density in a layer that thick, instead of actually integrating it.

On a smallish round conductor, where the circumference isn't many, many skin depths, there's a broken assumption in the skin depth formula of an infinite flat plane. Actually solving for the true AC resistance (or current distribution) involves elliptic integrals which only have infinite series solutions.

Which is why there are nifty tables and empirical formulas for AC resistance of round conductors (solid and tubular) that get you arbitrarily close. See, e.g., NBS Circular 75 or Grover or Reference Data for Radio Engineers.

Lest you think I am nit picking here.. take a piece of venerable RG-8 style coax, with the AWG13 inner conductor (0.072" diameter, 1.83 mm). The skin depth at 1.8 MHz (per the above post) is 0.18mm, so the wire is 10 skin depths across, so it's probably a reasonable assumption.

However, let's take something a bit smaller, like RG-8X or RG-58 type coaxes, which have a inner conductor on the order of 0.9mm. Now, you're talking only 4-5 skin depths, and the assumption of an infinite plane probably doesn't hold.

So.. Terman's equation probably holds for coax where the inner conductor is >20 skin depths, and, as posted, it would make no difference whether it's a tube (with wall thickness>5 skin depth) and a solid conductor.

If you're speaking of phasing together two or more *active* antennas,
you'd best employ identical brand and models of the devices. Elsewise,
knowing the phase change _through_ the active antennas would be a crap
shoot.

What if a decrease in velocity resulted in an expansion
of physical dimensions? (It does.)

What if a decrease in velocity resulted in a shortening
of a second of time? (It does.)

An expansion of physical dimensions could create the
illusion of an increase in velocity.

A shorter second could create the illusion of a
decrease in frequency.

If one could stretch a cable from here to a receding
galaxy, the cable would not snap because it is, along
with the rest of space, expanding.

My family was in this country long before the Ellis Island immigration center was established (and before the U.S. was created for that matter), and the spelling came about as I described, not as Art speculates. The origin of the name is almost certainly Welsh, and it has a number of different spellings there, too, among which are Llywelyn, Llewellyn, and others, probably for the same reason it has so many different spellings here. The "Ll" is pronounced more like "Cl", but not with a sound we have in English. But the Welsh pronunciation was surely gone long before anyone attempted to spell it. I have no idea whether the original immigrant was a miner as Art speculates, an indentured servant, or a common criminal.

If I ever get a dog, its name will have to be Gelert.

I would tend to think that simple delay lines would work here, as there
is no real appreciable coupling between the antennas, due to their non-
resonant condition and small size.

WOW, 400Mbps!

Do not know how that is possible using the 3MHz to 80MHz band space, but cool!

Now if you could please take it to an appropriate forum it would be appreciated.

Thank you.

In the early days it was America was where England sent it's criminals
and thiefs where in many places they were absorbed into the
population. When America became independent England then sent its
scoundrels to Australia. America then accepted pretty much all comers
from all countries that were not dominatedby criminal backgrounds ala
Ellis Island When life became difficult in countries such as Ireland
with the potato troubles with the English landlords was difficult and
the mining industy, gold, lead coal etc in Wales petered out because
of cheaper competition America had a need for miners and farmers so
they piled in and spread about the plains of America where the
predominantly English pursued a life of hunting and migrated over the
lower states. It was around this time that the country was flooded by
Germans such that the english language nearly was replaced by German
with the saving grace of immigrants coming from China, the central
European populace, Italians e.t.c chose the english language to learn
because english was dominant in central business areas of the growing
cities.
So the possibility is, that you Roy have a criminal background and
wandered into english hands where they received their just reward by
being removal from the British Isles!

Indeed.. one would have to calibrate this. Mutual Z between antennas
(unless they are very tiny and loaded heavily) also changes the phase
(relative to the free space phase at that point).

Some amplifiers are more phase stable than others, too.

> Consider a "stationary" observer located at the
> center of the Big Bang. What would he observe?

I think one consideration would be the nature of the universe immediately before the big bang. If space-time existed before the big bang, there would have been no center since that is a characteristic of space-time. (In 3 dimensions, 4 D space-time, our universe, is best pictured as the surface of a sphere; you can move in any direction you want but there is no center). Even today, the surface-of-the-sphere model represents to some degree why there is no center in our universe. Another consideration would be that, at the time of the big bang, it is believed to have started out as a small point (like an isotropic antenna in 1 D, my words). There is no center in 1 D either. And there is no reason to arbitrarily assume the geometery of the big bang release mechanism was 2 D or 3D. From this, I might suspect that there was no center of anything, including the big bang. After the big bang it became 4D space-time with no center.

Therefore, there is no center that could have been identified as an observation point? :-)

943. skin depth decay

Newsgroup: rec.radio.amateur.antenna
Date: 2007-11-15 00:51:29 UTC
From: art <aunwin@insightbb.com>
Message-ID: <366658d6-df94-42d6-95d8-68ea43d107df@p69g2000hsa.googlegroups.com>
Source record: 33794

For a moment I can ignore the capacitive and inductive constituents
of a radiator and concentrate on "skin depth" Ignoring my premise
that the surface is covered with free electrons that are expelled
from a energy storage system. I look at a piece of aluminum
as a raw material which is measured and placed within a vacuum.
Since it is accepted that skin depth is a volume that is decaying
it would appear that the loss of this volume could be a subject of
measurement. By the same token we could remove a radiator from an
array
and also place that part after measurement to quantisize the
. the amount of decay and compare the differences.
We could then examine the decayed remanants to determine its
properties.
Has this been done and what were the findings?
This would certainly help it determining how the material forming the
skin
got there in the first place!
Question arise whether the skin material comes from the atmosphere
or from a regenerative property of the material itself thus ruling out
the sino soidal applied energy. .(Ignoring the obvious question as
to
how the energy got past the capacitance while retaining it's initial
properties).
Bear in mind that present calculations are based on the understanding
that
a sino soidal current is present at every segment point that can be
chosen
which then allows the presence of a time variant at each and every
point
on a radiator.(This an alternative to my viewing the radiator as a
tank circuit)
Ofcourse if you already know of a book that shows how the skin
surface
materialises from the beginning and methodically replaced as it moves
from the surface to the innards of the radiator, please let me know.
Regards
Art

Essentially correct, there is no center of the universe.

From: http://math.ucr.edu/home/baez/physics/Relativity/GR/centre.html

"There is no centre of the universe! According to the standard theories
of cosmology, the universe started with a "Big Bang" about 14 billion years
ago and has been expanding ever since. Yet there is no centre to the
expansion. It is the same everywhere. The Big Bang should not be
visualised as an ordinary explosion. The universe is not expanding out
from a centre into space. The whole universe itself is expanding and it
is doing so equally at all places, as far as we can tell."

Those that can get access to a copy should look at the Radio Society of Great Britain, RadCom Magazine, December 2007 issue, Technical Topics column by Pat Hawker G3VA. The topic? 50 Years of amateur antennas. He covers a lot of the perennial topics of debate in this newsgroup and provides some excellent commentary on element lengths, feedline lengths, SWR, ATU's, modes of operation and some of the controversy. Okay, it has probably all been covered elsewhere in books, on websites and in this newsgroup, but there is a lot of useful information condensed into a couple of pages. Almost a substitute fro Kraus and Terman! :-)

Mike G0ULI

> probably doesn't hold.

That would be nit picking unless very high accuracy is required.

As Jim said, the current density actually decays from the surface in an exponential manner. The skin depth is the depth at which it's dropped to 1/e its density at the surface. If a conductor is infinitely thick, the total loss is exactly the same as if the current density was uniform to the skin depth and zero below. So this approximation is widely used when it can be assumed that the conductor is at least several skin depths thick. A rigorous calculation for a round wire really requires a computer, since it involves evaluating complex Bessel functions, and I believe that closed form equations for many other wire shapes don't exist at all.

But there are two levels of approximation you can make with the assumption that the current is all flowing in a uniform layer. If you calculate the cross sectional area of the ring of current, you come up with (from simple geometry)

Area = pi * delta * (OD - delta)

where OD is the outer diameter of the wire, and delta is the skin depth. The material's bulk resistivity is divided by this area to find the wire's resistance per unit length.

If the diameter is much greater than the skin depth (OD >> delta), an even simpler approximation can be and is often made:

Area ~ pi * delta * OD

I assume this is the infinite diameter assumption Jim mentions.

If you use this infinite diameter assumption, the error in the calculated resistivity of a copper wire 0.9 mm diameter at 1.8 MHz is 5.4% (compared to a rigorous calculation). This error isn't a big deal for most purposes. But by simply using the first rather than the second

equation for area, the error drops to less than 0.1%. You're still using the approximation that the current is flowing in a uniform layer one skin depth thick, so the entire calculation can easily be done on a pocket calculator in a minute or so.

No !!!!!!!!!
Every thing is known.
It must be in the books of Kraus and you know who.
I keep reading that the theories of radiation is well known
and widely accepted, so what is widely accepted in this area?
Is the "rust" of aluminium called bauxite by any chance?
And is it diamagnetic?

Pat Hawker was the only part that I read but lately he seems to be
rambling.
The antenna reporter isn't really putting out anything of interest for
the
regular ham either tho I was pleased with the experimenting for QRP
I terminated my subscription to Radcom this year because there rarely
was anything else that was interesting. Wrote them a letter earlier
this year
but they didn't even acknoweledge it.
Have been to the HQ by the way at St Albans or was it Hatfield?

I'm rather surprised that he's still doing the column. It's been
thirty years since I bought a collection of Technical Topics, and later
I found a used one dating from the sixties. I have no idea when
he started doing it (wait, I guess if this is "50 years of antenna topics"
then it must be fifty years), but I suspect nobody has had such a long
running column in the ham magazines.

Of course, such columns are relatively easy to write, since it's a filtering
of a lot of material down to it's essence.

Hi Roy,

He does mention that antennas possess radiation resistance, not to be confused with and not the same as, characteristic impedence (or feedpoint impedence) and that the characteristic impedence will vary along an antennas length.

As for the actual point(s) along an element at which an antenna radiates (transfers energy to free space) with maximum efficiency, he makes no comment.

I seriously doubt that there is anything in the article that you would dispute.

It seems that everyone was so busy laughing on this newsgroup, that no one has actually provided any information as to whether any detailed research has ever been carried out as to what is going on within the radiating elements of an antenna. There is loads of theory in the text books, but I have yet to see any empirical measurements or results. I am aware of the research into small loops carried out by Professor Underhill (also published in RadCom) but it seems that even his results have been disputed.

I may have submitted the post, tongue in cheek, to stir things up a bit, but on reflection there seems to be something of merit in the idea. I am revisiting the appropriate chapters in Kraus and Terman to see where the error in my logic is. In the absence of any direct evidence of

contradiction, I think it may be worth developing this idea and making a few measurements of my own to see what the truth of the matter is. Amateur radio is supposed to be a learning experience, right? And you can't learn without making mistakes. After 40 years of following the diktats of professional communications and electronic theory, I think the time is right to kick off the traces and challenge some of the accepted authodoxies. I do know all the conventional stuff, it just doesn't satisfy my soul.

You probably know more about antennas than anyone has a right to know Roy, but it's a strange universe out there and it's just possible that there's a few more things to learn yet.

Regards
Mike G0ULI

Hi Art,

That is true, but he has been a columnist for years and years, and there must come a time when you start to go round in circles. Rather too much emphasis on low noise mixers and old valve circuits for my taste but sometimes there is a real gem, like this month. The homebrew column that has been appearing for the last few months has been very good and very practical. The head office is in Potters Bar, just off the M25 motorway. They have quite a nice station that licensed visitors can operate, with prior notice. The staff are always friendly but are rather busy all the time so are not really in a position to stand around having long chats.

Cheers
Mike G0ULI

>elements of an antenna.

This, as the lawyers would say, argues a fact not yet in evidence.
Your statement appears to be one that can only be satisfied by meeting
a string of conditions:
1. The actuality of "actually," who is the arbiter of this? This
group has long experienced denial by inventors that their theories
have never been "actually" disproved. "Actually" is one of those
rubbery words that fits any argument that lack definition;
2. "detailed research?" Another qualifier that invites the rejection
of any contribution for lacking unspecified requirements;
3. "what is going on?" Now THERE is a technical goal for detailed
research to be provided as information.
4. "within the radiating elements?" Is this to presume there is some
distinct radiation from "within" elements? This would be a remarkable
measurement achievement to tease it out from the rest. [Could we use
a Gaussian sieve?]

>There is loads of theory in the text books, but I

If you moved to the fiction shelves would you say there is loads of
drama in them? [More to the matter, what would you expect?]

>have yet to see any empirical measurements or results.

Of what? Actual detailed results of what is going on within radiating
elements?

Help us out here. What instrumentation would be used? What units of
measure would be employed? (In "what is going on" are we talking
about Ohms, Volts, Amperes; or swimming, having a party, or getting
laid off?). What qualifies as detail? How would we recognize it
being actual?

> I am aware of the
>research into small loops carried out by Professor Underhill (also published

>in RadCom) but it seems that even his results have been disputed.

Hmm, tantalizing, but how do small loops relate to "what is actually going on?" More so, where within the loop did Professor Underhill make his measurements, and what were they of? [I might point out here, editorially, that little content was posted by you up until this point, and it has evaporated following its solitary mention. If you stripped out everything, and simply fleshed out this sentence into a paragraph, it might be meaningful.]

>I may have submitted the post, tongue in cheek

Then the joviality that your post heralds is merited, isn't it? This is called leading with your chin.

>, to stir things up a bit, but
>on reflection there seems to be something of merit in the idea.

As your post seems to be wholly unrelated to the topic, and apparently a stream of consciousness from another thread, then this idea is adorned with rather vague suggestions.

Well, that's obviously false. The characteristic
impedance of a horizontal wire above ground is
constant at 138*log(4D/d)

The characteristic impedance is not to be confused
with the voltage to current ratio existing on a
standing-wave antenna any more than the characteristic
impedance of a transmission line is to be confused
with the voltage to current radio existing along
its length when the SWR is not 1:1.

Interesting point.

When I use a gamma match on a 1/2 wave vertical with counterpoise, I have always wondered about the 50ohm impedance point where the gamma taps the element.

To end feed the antenna, an impedance of thousands of ohms is encountered, a, seemingly, "strange" distance up the element (in regards to total element length) and a 50 ohm impedance point is encountered (needing only a series capacitive reactance to correct for the gamma rods' inductive reactance.)

It would be interesting if I had a formula which would predict what impedance would be encountered for all points along the element--know of any?

I have looked at setting up such a formula, but frankly have been unsuccessful ... and of course, it is given that antenna length IS resonate for the frequency in question.

JS

>

No, that wasn't nit picking; those are all fair points.

The underlying point is that engineering is ultimately about numbers. We all like to think in words and mental images if we can, but in marginal cases these simple slogans and cartoons won't work.

On the other hand, the marginal cases don't invalidate the point that the skin effect *will* be present. If there isn't enough conductor depth to allow the skin effect to develop unhindered, it only affects our estimates of the AC/RF resistance.

If the available depth of conductor is too small, the inside boundary will push the current density profile outward towards the surface. For a round conductor, we can think of it as 'current crowding' along the centreline. A closely related case is copper-plated steel, where the magnetic nature of the steel increases its AC/RF resistance by a further factor of sqrt(mu), which squeezes a much higher fraction of the total current into the thin layer of copper.

>However, let's take something a bit smaller, like RG-8X or RG-58 type
>coaxes, which have a inner conductor on the order of 0.9mm. Now,
>you're talking only 4-5 skin depths, and the assumption of an infinite
>plane probably doesn't hold.
>
We can see a little further into this without the need for detailed math. The radius of the conductor is 2.5 skin depths (again using 0.18mm) so the current density at this depth would normally be 1/e^2.5 or about 1/12 of its surface value. That suggests that the perturbation in RF resistance due to insufficient depth is only taking place at around the 10% level. In the context of *estimating* the RF resistance to help us decide whether to buy a drum of cable, that wouldn't be a serious error.

However, it warns of a very serious error if the centre conductor was made of copper-plated steel instead of solid copper.

>
>So.. Terman's equation probably holds for coax where the inner
>conductor is >20 skin depths,

Sorry, Jim, you lost me: why such a large number as 20?

At 2.5 skin depths, the current density is <10% of the surface value; at 5 skin depths, <1%. If at least 5 skin depths are available, we can be confident in the accuracy of the standard, uncorrected equation for most purposes.

A more serious effect of insufficient conductor depth may be in estimating the effectiveness of shielding. The residual fields at the opposite side of an extremely thin shield can be very significant if we're looking for attenuations of 40dB, 60dB or more.

Hi Richard

Thanks for yor comments and encouragement. I can well understand your skepticism and accept that this idea is pretty far out. As you rightly point out, there are a whole host of issues revolving around what is being defined, measurement methods and interpretation of results.

The small transmitting loop efficiency experiments were carried out using thermographic imaging to try and identify areas of heating within the loops. The areas with maximum heating would indicate high current flow or high resistance. This information was used to try and derive a theory of operation and efficiency figures for the loops. The idea being to prove that efficiency was in fact higher than predicted by the Chu theory. The methodology and results of the experiment were challenged and Chu theory seems to have won out, at least for the time being.

I don't see that there would be any need to invoke non standard units for experimental measurements, ohms, amps and volts should suffice. I have not worked out the best measurement methods or instrumentation to use, but I am

sure that existing equipment and techniques will suffice. Small sampling coils, hall effect devices, temperature measurement probes and thermal cameras are all available at prices which an amateur experimenter can afford, so there is no reason why these experiments could not be carried out in a domestic environment rather then an industrial one.

The reason for specifying a single radiating element is because directional and reflecting elements absorb and re-radiate RF energy. Once the properties of a single element are known, then it is possible to add additional elements and make further measurements and assessments of performance. Since it is already known that all the elements of an antenna interact with one another, it is important to start with the basics and work up from there.

The choice of the word 'within' was unfortunate because I accept that there is nothing going on actually within an antenna element, skin effect ensuring that RF travels on the outside of conductors.

So I come back to my assertion that very little detail seems to have been published about what is happening really close in to antennas i.e. on the actual elements making up the antenna. Loads of stuff about near field and far field experiments, but not specific points of radiation from the antenna elements. It may all be a complete waste of time but at least I will have fun and hopefully learn some new stuff doing it.

Regards
Mike G0ULI

Cecil

Are you sure you are not confusing the characteristic impedance of a dipole antenna with the characteristic impedence of an open feed line? One is constant, the other appears to vary along its length. A dipole antenna has low impedence at a centre feed point and high impedence at it's ends.

Reminds me of the tales of old ladies who used to tie knots in electric flex to stop the electricity leaking out! I actually met one in real life many years ago.

Has anyone got any simple moderate gain construction ideas for antennas on the 23cm (1296MHz) band. Gain of a few dB in either vertical or horizontal polarisations are wanted. Brief accurate description of materials, construction sizes in metric dimensions and tuning tips would be most appreciated, along with anticipated gain figures/VSWR/return loss/input Z if known.

I'm not after the quad 36EL array designs, just whips, small yagi's or dipole sugestions.

This site looks like it has some good info. Check out quagi antennas,
it is pretty easy to build high gain antennas .

Here's a quote from "Antennas Theory" by Balanis: "The current
and voltage distributions on open-ended wire antennas are similar
to the standing wave patterns on open-ended transmission lines.
... Standing wave antennas, such as the dipole, can be analyzed
as traveling wave antennas with waves propagating in opposite
directions (forward and backward) and represented by traveling
wave currents If and Ib ..."

As Balanis suggests, the body of technical knowledge
available for "open-ended transmission lines" is applicable
to "open-ended wire antennas", e.g. dipoles, which really
are nothing but lossy *single-wire* transmission lines.

That characteristic impedance equation for a single-wire
transmission lines can be found in numerous publications and
is close to a purely resistive value. A #14 horizontal wire
30 feet above ground is very close to a characteristic
impedance of 600 ohms. (One half of a 1/2 wavelength dipole
is simply a lossy 1/4 wavelength stub with Z0 = ~600 ohms.)

Before he passed, Reg Edwards had some earlier comments on
the characteristic impedance of a 1/2WL dipole above ground.

Like a normal transmission line open stub, a 1/2WL
dipole supports standing waves that can be analyzed. For the
purposes of a voltage and current analysis, I^2*R losses and
radiation losses can be lumped together into total losses
associated with some attenuation factor, similar to analyzing
a 1/4WL lossy normal stub.

In fact, the losses to radiation from
one half of a 1/2WL dipole can be simulated by EZNEC using
resistance wire in a 1/4WL open stub. Using EZNEC with a
resistivity of 2.3 uohm/m for a 1/4WL open stub gives a pretty
good model of what is happening with one half of a 1/2WL dipole
which is only a lossy single-wire transmission line above earth.

The "rust" on aluminum is aluminum oxide. More related to Corundum {Al2O3}, sorry can't do subscripts in thunderbird, than Bauxite which is {Al2O3.2H2O}. The oxide coating forms almost instantly on aluminum when exposed to air. It is very thin and can be scratched off and will not form if air is keep away from it which is why clamping works. The oxide coating is also why soldering to aluminum is hard to do. If soldered in an atmosphere without oxygen aluminum would solder easily. When aluminum is exposed to water a white powdery coating forms. That is closer to Bauxite as it's a hydrated aluminum oxide of which Bauxite is just one. Anodizing is process that makes the aluminum oxide coating thicker and more porous so that dye can be forced into it so it can be colored. And anodizing also is a good insulator which is why it must be scraped off where you want to make an electrical connection.

> it's ends.

The feedpoint impedance of a stub is NOT the same thing
as the Z0 of the stub. The feedpoint impedance of an
antenna is NOT the same thing as the Z0 of the antenna.

The characteristic impedance of a #14 wire 30 feet above
the ground is close to constant at 600 ohms. The formula
for a single-wire transmission line is 138*log(4D/d).
A horizontal dipole is nothing more than a single-wire
transmission line which is known to be lossy.

The characteristic impedance of a transmission line is
constant. If the SWR > 1, the voltage to current
ratio varies along its length. That varying impedance
(V/I) is NOT the characteristic impedance which is
constant.

The characteristic impedance of a horizontal dipole is
~constant. Since a dipole is a standing wave antenna,
the voltage to current ratio varies along its length.
That varying impedance (V/I) is NOT the characteristic
impedance which is relatively constant for a horizontal
wire.

Hi Mike,

OK, but this still tells me nothing of what issue you think I am
skeptical about!

>The small transmitting loop efficiency experiments were carried out using
>thermographic imaging to try and identify areas of heating within the loops.

Good, that is instructive.

>The areas with maximum heating would indicate high current flow or high
>resistance.

More properly, their product - Watts.

>This information was used to try and derive a theory of
>operation and efficiency figures for the loops. The idea being to prove that
>efficiency was in fact higher than predicted by the Chu theory.

This names only one theory and doesn't actually illustrate any
differences.

>The
>methodology and results of the experiment were challenged and Chu theory
>seems to have won out, at least for the time being.

Again, all of this is suggestive, not informative. Returning to your
earlier complaint of "detailed research" we have no details beyond
heat imaging challenging the establishment.

>I don't see that there would be any need to invoke non standard units for
>experimental measurements, ohms, amps and volts should suffice.

Too often, this group has to wade through "what it is not" instead of
"what it is." Tell us what specific units would be convincing for
you, as you have introduced a complaint that needs to be satisfied.

>I have not
>worked out the best measurement methods or instrumentation to use, but I am

I have worked on a world of instruments (more than anyone here).
Believe me, that experience has NOT answered the question of the ages.

> Small sampling
>coils, hall effect devices, temperature measurement

OK, by induction, I presume you are harkening back to these thermal
maps or imaging.

Well, in fact they have been done, their results have been posted to
the net and argued here. You didn't get the invitation?

Unfortunately, that contributor was arguing smaller loops, coils
specifically and the mapping was tangential to the rant. He promised
more data when Spring weather would allow him to pursue this line of
inquiry, but that was several Springs ago, and he has in the interval
chosen to -um- till the same ground.

True, and certainly it stands to improve clarity by reducing
variables.

>The choice of the word 'within' was unfortunate because I accept that there
>is nothing going on actually within an antenna element, skin effect ensuring

Plus, thermal imaging would be hard pressed to peer inside a
conductor.

You mean you are unfamiliar with this work. I've posted my own here
to little attention, I don't think this cycle will attract much more,
but here it is:
http://home.comcast.net/~kb7qhc/antennas/Fields/Dipole/index.htm

This doesn't actually attend your preference of thermal mapping, but
you are still vague to the point of "what is happening really close in
to antennas" (even qualified by "on the actual elements" - there's
that word actual again which lends nothing to a specification).

There is an entire field of Science devoted to this (beyond the scope of many here who would anticipate my answer being "Fields"). This field is called Plasmonics. Books are written about it, pictures are taken of it, and I've sat through hours of presentations demonstrating it. Unfortunately, this crowd of investigators, like Arthur, have re-invented the wheel and they proclaim it is square.

The long and short of it is that you stand to become more confused, but it could be rewarding if you wear asbestos.

But it's round... (unless Terman rolled that into his constants)

Consider if you peeled that 2.5 skin depth layer and made it flat. It would look like a pyramid, not a rectangular bar.

Of course, if you assume that the cross sectional area is an annulus (the pi*(r^2-(r-skindepth)^2) style calculation) this partially gets taken into account.

The other factor is that in a wire that is comparable to skin depth in radius, the current on the far side of the wire also contributes to squeezing the current towards the near side surface. (and that's why the actual math gets hairy.. you can't use a simple exponential approximation for the current density)

At 20 skin depths, the difference is negligble.

As a practical matter, if you have an application that actually cares about this level of detail, you probably have the resources to deal with the exact calculations, so the simple "thin layer on the surface" is close enough.

For what it's worth, this kind of thing is why the loss in coax doesn't follow a nice k1*f + k2*sqrt(f) characteristic at low frequencies. The second term is essentially assuming that the skin depth in the conductors is "small" compared to conductor size.

Especially at low frequencies... (shielding mains frequency
interference, or PWM switcher noise, for instance)

Actually, such columns can be very difficult to write. Distilling to
the essence, without losing an essential detail, can be quite
challenging. Anyone can write a 200 page tome that covers something in
all its gory detail, given sufficient time and effort. It's
substantially harder to make an adequate summary in 100 words, and doing
it on a deadline.

Sort of like writing meaningful abstracts for a technical paper.

Thank you for the info John.
I am not very good in the chemical area but I believe that all
diamagnetic materials
form hydroxides where the constituents contain a sinle Oygen and
hydrogen (HO)
Thus materials used for antennas generate a surface where (HO) is a
constituent.
This can produce particles,ions or what have you to congregate on the
surface
but without energy per se but possibly adverse to the high velocity
release
of electrons.
Would that have any accurate deductions derived from the initial (HO)
constituent?
I also see a possibility that all contain a particular static particle
such as dust
that can be obtained from most if not all orbiting mass in the
Universe (something like
Moon dust that cling to a astronauts outer wear in the effort to join
the H2O of the
human body within) I did read that NASA in an effort to remove moon
dust had partial
success by directing energy from a capacitor release which overcame
the inertia of the dust on clothing.(They have a fear of this dust
entering the space vehicle
and acting as an abrasive substance.)
As you may guess I am trying to determine the action of a pulsatic
release of energy
from a capacitor that will eject "something" from a diagmagnetic
surface from
which a radiator is made.
Again, many thanks
Art Unwin KB9MZ.....xg

Hi Arthur,

This is discussed in most Physics books. Unfortunately, not in the terms you are expecting - so essentially trash to any invention purporting to elevate this dust-buster energy to radiation status.

Let's say you want to pulsatic eject "something" from a surface. It first has to exceed the work function of the material. This is pretty hard for metals exposed to any environment other than vacuum, and even more hard if insufficient voltage/temperature is applied.

Given this work function barrier, we would observe it as the cessation of radiation from an antenna when potentials/temperatures dropped below a critical level. Given further that many Ham operators collect QSL cards from all over the planet on Watt power levels, there is no evidence of this at all (as a Watt power level into a resonant dipole is insufficient to supply the work function requirement).

Hence, it follows that pulsatic ejection is of no consequence beyond the illusion of performance.

> loop or vertical monopole?

That's a good question. For a horizontal wire, its obvious
that the forward wave reflects from the open-circuit at the
end of the wire. We know there are standing waves on a loop
but exactly where are the reflections originating? I
suspect they are originating at the feedpoint, i.e. the
forward wave travels all the way around the loop and is
reflected from the impedance discontinuity at the feedpoint.
Note that the feedpoint impedance of a full-wave loop is
in between the feedpoint impedances of a 1/2WL dipole and
a 1.5WL dipole indicating that the forward wave travels
about 1WL before being reflected in the loop.

Every segment of a monopole is a different
distance from ground and therefore has a slightly different
characteristic impedance which probably doesn't change very
fast as it is a log function. For instance, for the sake
of discussions, it seems reasonable to assume that the Z0
of a vertical stinger is in the neighborhood of a few
hundred ohms and would be easy to measure. At whatever
frequency causes the stinger to be 1/8WL, measure the
impedance. That will be fairly close to the characteristic
impedance of the stinger at the measurement point.

Do you distrust the theory of relatively because you
haven't verified it experimentally and don't know
how to do so?

I have simulated the configuration using EZNEC.

Tom, like you, I trust the great engineers and physicists
who came before me. I do not develop every concept from
first principles. If an analysis suggested by Balanis is
not good enough for you, that's your choice. Incidentally,
Kraus says essentially the same thing as Balanis about
analyzing standing-wave antennas.

As a data point, using EZNEC's VERT1.EZ 40m vertical,
the feedpoint impedance at 3.6 MHz is 6 - j356 ohms.
That would make the Z0 at the feedpoint around 360
ohms and Z0 no doubt increases with distance above
ground.

Art wrote:
"---Joules are not necessarily accelerating."

True.

Terman says:
"Radio waves are produced to some extent whenever a wire in open space carries a high-frequency current."

Kraus says:
"Thus, time-changing current radiates and acceleerated charge radiates."

A joule is a unit of work or energy in the MKS system. A joule is the quantity of energy needed to transport one coulomb of charge between two points of one volt potential difference.

Incidentally, "average power" is the kind of power we ordinarily use.

Radio waves as Terman uses above are of the energy which escapes from the near field of the wire and is unlikekly to be recaptured by the wire.

A bit more on the "interaction" between two waves...

From "Optics", by Hecht: "Briefly then, optical interference
corresponds to the *interaction* of two or more light waves
yielding a resultant irradiance that deviates from the sum
of the component irradiances." (emphasis mine)

Since the "interaction" between two waves is good enough for
Hecht, it is good enough for me.

That would be a reflection from a virtual impedance bump wouldn`t it?

The wave travels both wires of a feedline simultaneously, and enters both ends of the loop at the same time. The collision is at the midpoint of the loop opposite the feedpoint.

Arnold B. Bailey says on page 399 of "TV and Other Receiving Antennas":
"Now, in the loop, the far-end reflection point is a short circuit, and hence, the current is high at this far end."

I actually do know how to verify Einstein's predictions because the fellows who did it wrote detailed articles on how they did it.

Thinking of antennas as transmission lines is an old practice. It doesn't mean it's very practical, or that it hasn't been superseded by a better analogy. For that matter, a vibrating guitar string can be analyzed as a transmission line, as can any woodwind instrument. That doesn't mean it's worth doing, but it can be done. The problem is when a gentleman, such as the late, lamented Reg Edwards, or the still kicking, unlamented you, write that an antenna, or a clarinet _is_ a transmission line.

Hi Marcel,

A somewhat unknown antenna, with reasonable gain and easy to
construct is the trihedral reflector antenna (corner radar reflector
as antenna). It uses a monopole as radiatior.

A short acticle (Spanish) with a photo of such an antenna can be found
at: w3.iec.csic.es/ursi/articulos_gandia_2005/articulos/RP1/350.pdf

A long investigation (English) with a high gain trihedral antenna can
be found at: http://yu1aw.ba-karlsruhe.de/shorten3dcra.pdf.

No, the impedance bump is physical. The physical Z0 of the
feedline is no doubt different from the physical Z0 of the
loop.

> The wave travels both wires of a feedline simultaneously, and enters
> both ends of the loop at the same time. The collision is at the midpoint
> of the loop opposite the feedpoint.

Waves traveling in opposite directions in a constant Z0
environment don't interact. If the Z0 doesn't change, they
pass each other "like ships in the night".

> Arnold B. Bailey says on page 399 of "TV and Other Receiving Antennas":
> "Now, in the loop, the far-end reflection point is a short circuit, and
> hence, the current is high at this far end."

If there is no physical impedance discontinuity, there is
no reflection. Reflections occur only at physical impedance
discontinuities. That virtual short circuit is an effect,
not a cause.

Thank you Richard,

That has helped to clarify my thinking. I know people tend to insist on very specific language and technical terms before being willing to accept anything new on this newsgroup. I tend to agree that this is a good thing and resorting to woolly, imprecise or made up terms does nothing to clarify new concepts.

I guess you are skeptical that there might be a specific point on an antenna that matches the impedence of free space and thus radiates energy more strongly than the rest of the antenna. This is the subject that interests me and I intend to try and establish to my own satisfaction whether this is or is not the case. If this can be established in a scientifically robust manner, then I will present my experimental method, measurements and conclusions for critical examination. I am unfamiliar with work that has

been carried out in this field, so I will carry out further searches and reading before embarking on reinventing the wheel. Thanks for the link and the suggestion about plasmonics and fields, I will follow up on that.

Cheers
Mike G0ULI

But Tom, page 18 of "Antenna Theory" by Balanis,
shows how a transmission line can be opened up
to cause it to radiate. A dipole is indeed a leaky
transmission line. During steady-state, it loses
about 20% of the power stored in the standing
waves to radiation. Maxwell's laws don't change
from transmission lines to wire antennas.

Hi Art,

Thanks for your comments. I am prepared to listen/debate whatever anyone has to say and consider their comments. As the USA is so fond of advising the world, everyone has a right to free speech. I listen, consider and then judge whether the comment is helpful or not in the circumstances.

Having a completely open mind allows others to fill it with junk. But applying some critical judgement to the dross allows you to glean some nuggets of gold occasionally, just like life in general. The skill lies in being able to decide what is relevant and that comes with education and life experience.

Cheers
Mike G0ULI

I am beginning to believe that levitation is at hand here.
When a magnetic fiels is imposed particles on the surface of the
radiator
are levitated where they MUST move to the outside of the arbitary
border
from Gauss which encloses the aluminum radiator and the static
particles.
The magnetic field upsets the equilibrium within the confined border
where the border fractures in an effort to retain equilibrium which
allows
for full levitation outside the border Do some articles that are in
the motion of levitation fail to escape when the magnetic fields is
lost and thus return to the radiators surface possibly to replace
particles lost from the "skin" of the radiator. I think we have a
possible avenue here!

If you haven't seen any measurements or results, you haven't looked in any of the professional publications over the past hundred years or so. There have been a great number of measurements of antennas made. Of those, none to my knowledge have ever definitively shown results other than the textbook theory predicts. That's pretty good confirmation of the current theory.

If there is merit to alternative theories, they should predict exactly (or at least within the most precise measurement capabilities we have) the same results as the current textbook theories, because those theories agree closely with measurement. That means the alternative theories must come with equations which can be used to predict antenna performance as well as what we use now with great success. Vague hand-waving is adequate to convince a certain number of rraa readers, but it doesn't go far with those of us who actually design antennas that have to work.

There's a real problem here. Making even half decent measurements of antennas is an extremely difficult undertaking. People without the proper equipment, experience, and knowledge of tolerances to be expected frequently make poor measurements and draw erroneous conclusions from them. Before you get too involved, I suggest starting with a dipole, loop, or some other very simple, well understood, and well documented antenna and see just how good your measurement methods are. If you can't do those simple antennas properly, then any other measurements you make shouldn't be trusted. And those are the easiest ones. If you want a real challenge, try a very short antenna. Just keeping the feedline from being part of the system can be a nearly insurmountable task, and measuring a very small resistance in the presence of a very large reactance isn't easy either. Unless you can deal with these and other measurement realities, your measurements might be fun, but they won't mean anything. You can publish on rraa and draw a certain number of oohs and ahs, but it won't be material for the IEE or IEEE -- not because they're contradicting conventional theory, but because they're not representative of reality.

Have you considered religion? The rules of evidence are much more relaxed in that environment, so alternative theories are more readily accepted. Just look at the proliferation of denominations. There's always room for a few more.

> You probably know more about antennas than anyone has a right to know
> Roy, but it's a strange universe out there and it's just possible that
> there's a few more things to learn yet.

Indeed there are. When you have an alternative theory that agrees as closely with measured results as the current ones, and which can be used to predict antenna performance, I'd like to be among the first to read your paper and benefit. Shoot, I might even incorporate the equations into EZNEC to make it even more accurate than it is now. I'm a member of the IEEE Antennas and Propagation, Broadcast, and EMC societies, so I'll see any papers published in those journals. And I can easily get papers published by the IEE or other societies. Have at it!

Yep, as long as you over look when those theories are based on math
which includes permeability and permittivity values for "nothing"
(space, a vacuum!) And denies the presence of any "ether type" media
which these COULD properly be allowed for!

Oh yeah, absolute proof alright--if 'ya don't look too close!

In accounting it is called "cooking the books!" <ROFLOL>

Thanks Roy,

I appreciate that this is likely to be a protracted project and that accurate measurements could be problematic to say the least. I intend to examine the performance of a resonant dipole first, then non resonant dipole elements and depending on results progress to more complex antennas. I am fortunate enough to live very close to a surplus equipment supplier who has a warehouse full of redundant commercial measurement equipment and certification facilities, so I may become one of their more regular customers. :-) I have more than enough qualifications to qualify for membership of IEE and sundry other organisations so publication wouldn't be a problem, but thanks very much for the kind offer.

I really am not interested in overturning current theory, I see this as an opportunity of perhaps adding another aspect to it. Obviously any 'improvement' would have to match current results and enable enhanced predictions to be of any practical use. I have spent well over 40 years trying to understand how radio works. The wonder I felt as a child listening to the radio and trying to understand how it could work has never disappeared. Despite many courses, seminars and conversations with experts, I still can't say that I really know how radio works.

As for religion, I attended a Jesuit run grammar school, put me off for life. Needless to say, the main thing I learned was to question everything and accept nothing at face value. So while it is true that current antenna theory is good enough for all practical purposes, I think it is possible that there may be room for improvement.

Regards
Mike G0ULI

Oh my, you sound so upset.
Your theory used in Eznec was designed
around known "reality" because you found the need to add the proviso
that there was a sino soidal current at all points on the radiator.
Number one, it is not legitamate to add a proviso or a special
condition
to a known law.(Electrical or Mechanical)
Number two It becomes a worse problem when the proviso added is in
error.
Number three, You should not retain a proviso if it proves incorrect .
The fact that present theory has passed the test of time means
nothing.
The threat of retaliation trumps science when humans are concerned.
Gallilao never saw the day that the earth was proven round which
stood the test for a very very long time.
But you could explain to the world how a sino soidal current passes
thru
a distributed capacitance and still retain its properties as it
encounters every segment. This is per the proviso you have placed
with
existing Maxwell's laws with respect to your computor program.
But no you can't! Until then I don't think you are equipped to say
that written theory can be taken as fact.Especially when known laws
are twisted so you can gyrate your program to known reality.
The old saying still stands, Garbage in will produce garbage out
unless the outputs are subject to reprocessing !

Art,

I'm sure Roy is quite capable of defending himself against your accusations, but I think you are being a trifle unfair. EZNEC is a simulation designed to predict the performance of an antenna design. Being a simulation, certain assumptions and approximations have to be made in order for it to work. The fact is that in most situations it does provide an accurate prediction of antenna performance. There are some special circumstances where it won't.

Integral calculus has been described as one of the greatest advances in mathematical science, but that is still only an approximation method and

nobody complains about that.

Let's all behave and not argue okay?

Best wishes
Mike G0ULI

Hi Mike,

When your energy is frequency based, and your interface is large in terms of wavelength (and anything over 1/10th wave is still large); then trying to home in on a "specific" point is not very specific at all.

>This is the subject that interests me
>and I intend to try and establish to my own satisfaction whether this is or
>is not the case.

You will probably be able to approach it by degrees, but as you get closer focus has to be abandoned (classic wavelength vs. physical length diffraction limitation).

>If this can be established in a scientifically robust
>manner, then I will present my experimental method, measurements and
>conclusions for critical examination. I am unfamiliar with work that has

More towards the RF end of the scale, diffraction limits (being broken) and your interest, consider:
http://physicsworld.com/cws/article/print/17398

You can listen to others crow about how "someday" science will catch up, or you can simply see that science has already left that crowd in the dust. The article above (and others found by googling "Boeing, and "negative refractance") will give you an RF material that turns beams in the opposite direction of what would be expected.

Our crowing buddies would shrug this off (lack of experience in this matter) because they don't realize that it solves the diffraction limitation. Build your own model and throw RF against it yourself to discover a lens with absolute (not fuzzy) focus.

But I am behaving. I am sure that both Roy and others who deal with
NEC4
will admit that they have played with the truth with respect to
antenna programs.
I would venture to say that computor programs are good at what they do
but
it is for all the wrong reasons. Maxwell's laws are just that..Laws.
It is mathematically fraudulent to add anything to those laws under
the banner of Maxwell.
When Roy left the ARRL circle he challenged antena companies to verify
their claims
with respect to gain. By the same token I am challenging to prove the
veracity
of the additional statement that a sino soidal current is present at
every segment point.
Not is it only mathematically illegal to modify a law the addition
also defies all electrical laws.
A radiator has distributed capacitance and I am not aware that a
capacitor will
allow the passage of a time varying current, this is what the
programing states.
He ofcourse can justify why he did this to the satisfaction of all but
he cannot justify
the insertion of such.
Now my antenna operates quite nicely following another aproachyet Roy
vehamently
derides this new aproach when he himself cannot verify his own
actions.
Fairness can be seen in different ways. He can be belligerent in
analysing my aproach
yet at the same time defend an action that he cannot prove to be true.
A person always has the right to defend himself especially against
those
who are mentally challenged. When he provides how distributed

capacitance does not affect
the time varient that Maxwell states is a titular point of his laws I
will readily
retract that remark. Until that time I will defend the veracity of my
aproach which
succesfully produces antennas and arrays in a smaller volume that
present theory
predicts as impossible. As an adder, I am discussing antennas and not
"systems" as Roy
would imply.
Nothing personal, Like Reagan I like verification since trust
does not prove to be enough and I will always defend if I am attacked.
Best regards
Cheers with a Black and Tan

No need for any defense; EZNEC (and other apps) are the "state of the art" as far as hams are concerned--they are more than adequate for our needs. Too bad so many view this/these discussions as an "attack."

These "arguments" are only an attempt to peer over the horizon on possible new discoveries and inner workings of antennas.

Nothing in my posts are meant to be an attack on EZNEC, Roy, or for that matter, any others and those who use them to construct and place into service the antennas in common use and which perform well. I am sure most others are of a like mind.

Arts' feathers have just been ruffled ... something we all have been guilty of--at one time or another.

Hello,
I wonder if anyone can help me, I am looking for the winding data of the loading coil used on the AV-18S Hygain antenna.
No of turns, no of turns per inch, length/ diameter and diameter of coil etc!

Many thanks
John

Just to clear things. I am not saying that Roy's work does not predict
with good accuracy how certain antennas perform. What I am saying
it is that it does this despite manipulations for the wrong reasons.
Isn't that sort of thing what makes us different to E ham.
One can hold his own theories but not by attempting to deride those
whose
theories differs. There must be room for differences in thought amoung
reasonable men or advancement in science is squashed and adherence
to written theories could last for ever. A moderator can ensure that
present theories remain sacrosant if that is what members desires!

I guess Art was implying sputtering. I actually posted the response sort of "tongue in cheek".

It was my understanding sputtering requires a vacuum and high voltage.

It would appear by Art's response, they figured out all the ins and outs of sputtering.

Yer preachin' to the choir.

There is more than enough to "prove" there are errors/holes in our present knowledge--well, IMHO, at least. No one is suggesting we just "throw it all away" ... I don't think I am alone--some just remain silent to escape the stones and arrows.

I have many more questions than answers, but don't we all? Be interesting in coming back in a hundred years and viewing "em radiation"/antenna theory at that time.

You just don't take well to bein' "poked with a stick!" ;-)

I don't intend to go too far off topic but the near field results are so strikingly different when you add the ground screen. This is an area that I am not so familiar with. At 80M does the program assume that the ground at near field is basically a dielectric instead of a conductor, acting like a large capacitor, whereas the screen is a pure conductor? It would seem this would have to be related to the explanation, correct? It sure shows at least one possible advantage of using a lot of radials; it reduces near field (?)

The characteristic impedance is a function of the transmission line construction, not of its length or the VSWR imposed on it. The actual impedance of course varies along the length. Zo is what it is and it does not need to be verified experimentally anymore than the impedance of free space needs to be verified. This work has already been done.

Mike, it is hard for me to let this go (but it is off topic). Integral calculus is not an approximation, it is exact. The prior art, the summation method of adding the areas of small rectangles, was the approximation. The genius of integral calculus was that it was able to sum an infinite number of infinitely small rectangles and come up with an exact answer. For the answer to be exact, it was necessary to deal with infinity (undefined) and the concept actually works. It even works in many cases where there is an asymptote that is infinitely long (f(x) = 1/x**2)).
END OF COMMENT (no, I will not offer experimental proof that integral calculus is exact :-))

No Chris I know you are not refering to the other use of a 8877 ie
spluttering
as with reed switch contacts. When a time varing current toapplied to
something
that creats radiation I am trying to deduce an alternative to the
thinking that
current can hurdle a capacitor and retain it's time varience.
This is why I view it in the context of adding a time varient to the
laws
of static particles where this action results in a tank circuit.
In that case the pulsatic release of energy serves as a time varient
that satisfies
the laws of Maxwell without the assumption that current can leap frog
a capacitor.
(Roy states that this is something he doesn't understand, as well as
avoiding
mechanical laws since they are irrelavent in the electrical world)
Whether I will be succesful in presenting a realistic alternative to
jumping
currents is moot . But after successfully produced an antenna, not a
system,
that exceeds that which follows printed theories I think I can be
forgiven in
not just accepting but to also pursue an understanding.
Certainly, I must not pursue the idea of distributed capacitance is
completly
devoid of ALL characteristics of a lumped capacitance as the computor
programmers would have us believe !
Food for thought for those without the herd mentallity who tend to
dismiss
the "unlikely" and make their fortune on only betting on polled
favorites at any
racing event....!
I do like the thought of levitation since it fits in the idea of a
Gaussian field
because then the escaping/ ejected particle meet the same conditions
that create
levitation when in the vicinity of a diamagnetic material ala a
radiator.
Question remains tho that particles are removed from the arbitary
field
possibly skin particles. This suggest then than that radiator surfaces

are
resealed on the surface from that provided from the external
capacitor.
All in all something worth while to ponder upon
Best regards
Art Unwin....KB9MZ

I've built one of these simple antennas , except I used copper clad
board for the reflector.

http://www.dl5neg.de/23cm_ant/23cm_ant.htm

I also used a simple corner reflector for years, but I can't find any
construction details on the web.

Art wrote:
"By the same token I am challenging to prove the veracity of the statement that a sino soidal current is present at every segment point."

An antenna is generally a linear passive device meaning that a sinusoidal wave entering an antenna produces sinusoidal fields which induce sinusoidal voltages and currents in the distant receiving antenna.

Sinusoidal voltages appear at every point on such an antenna and sinusoidal currents pass over the surface of every point of the antenna. Insulators of course interrupt conduction currents and allow the rise of voltage gradients.

Induced currents are produced by the electric field of the wave in the insulation of free space by the displacement (capacitive action) current of an antenna. Maxwell speculated that displacement generated a magnetic field same as conduction did, and that was the secret of radiation. He was proved correct. A magnetic field generated an electric field and an electric field generated a magnetic field so that the two fields locked and traveling together go on ond on forever.

Most antennas have two waves traveling in opposite directions, an incident wave and a reflected wave. Both pass through every point on the antenna conductor.

A directional coupler can access the wave traveling in one direction while ignoring the wave traveling in the opposite direction.

Large variations in voltage appearing on the antenna make the familiar standing wave pattern but this is not a true picture of the individual waves making up the combined wave. The effective values of the incident and reflected waves decline steadily but gradually along the antenna as they travel in opposite directions.

A sinusoidal current is present at every segment point and only slowly changes from point to point. Two sine waves of the same frequency always combine at a point to create another sine wave of the same frequency.

Best regards, Richard Harrison, KB5WZI

I am getting back to the HF bands after some 20 years 'rest'. What is the best type of wire to use for long wire antennas? The wire will be under some tension to keep it above some local trees!

You have hobbies. I have hobbies.
Chances are I have one that you don't.
I'll leave it up to you to decide!

"Best" has a number of different definitions depending on the particular
situation. If you want wire that'll never stretch or break and will take
a lot of tension, Copperweld is hard to beat. It's springy and a
nuisance to work with, though.

From the above, are the two in a constant state of interaction? The
magnetic reversing to electric--the electric reversing to magnetic?

Or, is their relationship static to one another?

Since '70, I've had good luck with stranded hard-drawn copper for up to lambda/2 dipole on 80m (no experience with longer spans). The latest stuff I've been using is 12ga (268 strand) hard-drawn for a single wire 80m dipole and now a cage dipole for 80m using 14ga from Davis RF (http://www.davisrf.com/). They also offer porcelain compression insulators, so a broken insulator won't bring your antenna down (and leave the end of the wire dangling in the trees). Nice folks to deal with, too.

All true and it works very well. It's just that being forced into accepting
such concepts as infinity and the square root of minus one without being
able to pin down exactly what they are shows up how limited we are in our
abilities to deal with the true nature of the universe. How can anyone
really get to grips with such concepts as an infinity of infinities?

Errrr, I was referring to thin film creation by creating a corona in a partial vacuum.

"The technique is based on the transfer of metal by: an electric discharge through gas at a pressure of less than one torr. Glass to be coated is placed between two electrodes in an atmosphere of gas at low pressure. The gas can be air. The cathode is composed of the metal to be deposited on the glass. Voltage sufficiently high to electrify or ionize the gas is connected to the electrodes. The impact of ionized atoms and molecules of gas against the cathode dislodges particles of the metal, which come to rest on the glass as an adhering film."

This is usually done best with DC not AC, but AC will work. Hence, I do not understand your referral to the 8877. Sorry.

Chris

If one threads a toroidal transformer over
a dipole wire, one will observe a sinusoidal
waveform (if the source is sinusoidal).

I've got an update on my antenna experiment. I decided to buy a new tuner, the MFJ 902H to see if that would help. It was priced low enough and had a built in balun. I tested it out using my SWR analyzer and this tuner was able to find matching points in the 80, 40, 30, 20, 17, 15, 12, and 10 meter bands. I did try to find a matching point on 160 meters but wasn't able to do so which is OK, since I've never worked 160 and the manual says not to try it on 160 anyway.

I plan to put this antenna on the air over the weekend to see what it can do. I know it will be a compromise antenna but I'm hoping it will allow me to do what many other hams in my situation aren't doing, getting on the air. I also know all the jokes about MFJ, Mighty Fine Junk, Made from Junk or my personal favorite, Mississippi's Finest Junk, but it was priced right and when I got it, it appeared to be well put together. I'll let everyone know how it works out.

Later...

Priz

"I am trying to deduce an alternative to the thinking current can hurdle a capacitor and retain its time variation."

An early demonstration of electroostatic repulsion was via an instrument called the electroscope. Put a charge on its plates and it opened like a book. It proved like charges repelled and that repulsion was proportional to charge.

From that it can be imagined that if you put a charge on one insulated plate and like charges on an insulated plate nearby have an avenue of escape to the outside world, you may have produced a capacitor useful for ac coupling or bypass. It isn`t a hurdle. It is a device capable of a displacement current which blocks dc but passes ac. It`s a device formerly called a condenser, now called a capacitor.

Richard Feynman said there is a probability that reflection will occur at any point within a partially reflecting media. He explained that all the probabilities (including phase) sum in order to generate the net, observed effect. Your observation about the full-wave loop is probably a good example.

In this day of high copper prices, my two favorite antenna wires are free wire and cheap wire. We had a fellow near here who, until the past year or so, was selling 500' spools of insulated #14 or #12 for five or six bucks per spool. I ran better than ten spools for my 80 and 160m inverted L's and stocked up for inverted vee wire.

A less expensive alternative might be the hardened aluminum fence wire in the larger diameters, allowing for some means of preventing the corrosion from copper to aluminum at the feedpoint.

Richard;

Thanks for taking the time to post that data.

Of course, in my "addled way of thinking", I still see the probability
of a media in which these actions are taking place (electric to magnetic
and magnetic to electric)--such as when you swing a wire (media)
through a magnetic field.

But, really, it is all still a question ... anyway, pondering keeps me
outta the bars. :-)

Arie, Many hams are not aware of your computor program which you do
not have a personal pecuniary interest. Certainly many are not aware
what exactly an optimiser does. It would be advantageous
if you could demonstrate its feature by requesting of it to supply
a single radiator that gives maximum horizontal polarization gain
Ofcourse, this means no guidance by you such as leading it to
a planar form or a fractional wave length so hams can determine
that it does meet reality as we know it.
I have not used your antenna programs tho it is much more
advanced than the one I presently use. Thus I to am interested
in what your optimiser will do in this most basic area that
all hams could understand
My best regards with thanks for providing hams with the benefit
of your knoweledge and free to boot.

The MFJ tuners are ok as long as you don't abuse them..
And on some , you probably should take the power ratings
with a small bit of salt depending on the load you are matching.
I've got a small MFJ random wire tuner that I've had since 1977.
It still works, and I often use it as a mobile matcher. Also
handy as a "line flattener" when running coax to a solid
state rig.
I've got a 989C that I got free from a guy that fried the coil.
He was ignoring the instructions and running high power
into a nearly half size dipole. I'm talking 8877 power.. :/
Started melting the coil form. Went through two of them.
So he went out and bought a big Nye Viking, and gave
me the 989C as basically junk.. To him anyway..
I messed with it a couple of hours getting the wires
back in the right positions, and then resetting the
roller tension, etc, and got it working again. I've been
using it ever since. Well, when I use a tuner anyway..
I use the watt meter and antenna switch more than
anything.
It's rated 3KW, "dash of salt", but it will handle and
tune about anything I will ever be messing with.
Being it's a T network tuner, it's lousy for feeding

half size dipoles though.. :(It will do 160m though.

There are many different kinds appropos for antennas, all with
different electrical and mechanical characteristics; see:

http://thewireman.com/antennap.html

Also, I've used the 500' spools at Lowe's Home Improvement; they're in
the $30 or $40 range now, I believe.

Of course, there are always 2nd, 3rd, ... Nth order effects.
On this newsgroup, we are usually talking about first order
effects. I had a recent email exchange with someone talking
about the part of the ground wave that escapes absorption
because of the earth's curvature and is probably ignored
by NEC simulators but not by AM broadcasters.

I would like more than that!
I would like to know what Terman had to say about radiation
which is a cause of most discussion the summation of which
is not accepted by the IEEE. I don't think he has given any
credit to Maxwell, Faraday, Heaviside or any of the pioneers
in any of his books so it would be interesting to know why
his wrestling with the mechanics of radiation was to no availe!.
And Richard, when you have finished reading from Terman
to get us to sleep, would you consider for your next book
to read to us, like Lady Chatterlies Lover by D.H. Lawrence?
That book may well prevent you going to sleep as well while
reading on the net Most of us have read all the volumes by
Terman so a different reading book may well be of more interest.
Art

You might find the article 'Sufficient sag for wire antenna spans for wind survival' at http://www.vk1od.net/rigging/sag.htm of interest. You might wonder why annealed copper in almost any form (enamelled, or PVC insulated, especially PVC insulated) is so popular.

I endorse Roy's support for Copperweld, but you will not find it readily available in Oz. There are a few suppliers of HDC (ATN and Discount Cables come to mind). Stainless steel (2mm dia) is used in some of the commercial antennas (eg Bushcomm), but you need to consider whether the additional loss is an issue for the specific antenna.

BTW, MIG wire (copper plated steel wire) is not Copperweld, Copperweld has a substantial copper thickness (eg 30%, depending on the grade) which is chosen to be at least several skin depths in thickess so that the RF resistance is similar to copper, but the strength comes largely from the copper core. Hams promoting 0.8mm MIG wire (as they do here) are on the wrong track, it is a grossly inferior product, you are much better off with galvanised fence wire than MIG wire.

Speaking of which, heavy galvanised steel fence wire (say 1.6mm for shorter spans) is not all that poor, but beware of newer fence wires which have thinner zinc, or worse the polymer coated wires with have an extremely thin layer of ZAl covered by the polymer coating. Though any of these are going to be better than rusty MIG wire.

1054. Superposition

Newsgroup: rec.radio.amateur.antenna
Date: 2007-11-16 20:34:35 UTC
From: Cecil Moore <nospam@w5dxp.com>
Message-ID: <v9n%i.10983$yV6.8880@newssvr25.news.prodigy.net>
Source record: 33658

The following is from an email to which I replied today.

Given two coherent EM waves superposed in a 50 ohm environment
at considerable distance from any source:

Wave#3 = Wave#1 superposed with Wave#2

Wave#1: V = 50v at 0 deg, I = 1.0a at 0 deg, P = 50 joules/sec

Wave#2: V = 50v at 45 deg, I = 1.0a at 45 deg, P = 50 joules/sec

These two waves superpose to V = 92.38v and I = 1.85a
Note: P = 171 joules/sec

During each second, Wave#1 supplies 50 joules of energy and
Wave#2 supplies 50 joules of energy for a total of 100 joules of
energy being supplied *every second* to the superposition process.
Yet the results of that superposition process yields 171 joules
of energy *during each second*, 71 joules more than is being
supplied to the process. Where are the extra 71 joules per second
coming from?

The peak intensity of a standing wave will always be greater than the simple sum of the two waves. Itot = 4*I*cos^2(deg/2). But I think nature will somehow conspire against you if you try to make use of more than the 100 watts input. ;-)

Never saw a phase lag suggested. As radiation impedance is a resistance even in free space, I expect rise and fall in electric and magnetic fields is simultaneous even as they speed away at the velocity of light. Which came first, the electric or the magnetic?

Sorry, unlike others on this newsgroup, I don't support
a violation of the conservation of energy principle. To
answer my own question above, the extra 71 joules/sec
of constructive interference comes from 71 joules/sec
of destructive interference occurring somewhere else.

I think you mean the strength comes from the steel core?

FWIW, when they say 30%, that means that the wire has 30% of the
conductivity of the same diameter copper wire, not that it is 30%
copper. You have to look in the mfrs tables to see what the cladding
thickness is.

Odd that there aren't suppliers in Australia.. Maybe because there isn't
an existing telegraph/telephone cable infrastructure in rural areas? In
the U.S., there were and still are millions of miles of the stuff
installed before carrier telephony, coax, optical fibers, etc became
common. And, it's still used for MV power distribution, much of which
is still above ground.

No reference to peaks here, Jim. Everything is average values.
The average value of the energy in the standing waves *always*
equals the average values of the energy components of the
forward and reflected waves added together. If there are X joules
in the standing waves, there will be X joules in the sum of the
forward and reflected waves.

> But I think
> nature will somehow conspire against you if you try to make use of more
> than the 100 watts input. ;-)

It was a rhetorical question for people who say, "Just do
a vector analysis and the energy will take care of itself."
Understanding exactly how the energy takes care of itself
is the point of this thread. Hint: 171 joules/sec from two
50 joules/sec waves requires an additional source of energy.
In the case of this example, the 71 joules/sec of constructive
interference requires 71 joules/sec of destructive interference
energy occurring somewhere else.

> Wave#1: V = 50v at 0 deg, I = 1.0a at 0 deg, P = 50 joules/sec
>
> Wave#2: V = 50v at 45 deg, I = 1.0a at 45 deg, P = 50 joules/sec

50 joules/s are carried by Wave#1 if alone. The same applies to Wave#2

But if both waves are sumultaneouly present, the power carried by each wave when alone is no longer a meaningful number. As a matter of fact when superposing two coherent waves (same frequency, fixed phase relationship), one MUST first sum voltages (or currents) and then calculate power.

Summing wave powers could only be done in case of incoherent waves.

In conclusion, the answer to your question is that the apparent extra 71 joules/s come front the fact that 100 joules/s taken as reference is a number having no physical meaning.

> Which came first, the electric or the magnetic?

The ratio of E to H fields of a wave is known as the wave impedance. It has both a magnitude and a phase angle (or real and imaginary components). The impedance of a plane wave propagating through a medium is the intrinsic impedance of the medium. For example, the ratio of E to H of a plane wave propagating through space equals the intrinsic impedance of space. The intrinsic impedance of space is purely real (~377 + j0 ohms), which tells you that the ratio of E to H of a plane wave propagating through it is purely real. This means there is no phase difference between the two - E and H are in phase.

But the intrinsic impedance of many materials (e.g., dirt) isn't purely real, so there is a non-zero phase angle between E and H fields of plane waves propagating through them.

The ratio of E to H is also often complex in the near field around an antenna, and usually with a magnitude other than 377 ohms. So in that region, there's also a phase difference between E and H.

I assume you are not trying to be funny and are using the dictates of
Terman to make a point. So I will respond. The antenna am referring to
consists
of a tank circuit where the distributed capacitance is the capacitor
in the circuit.
The capacitor stores energy from the time varying current and then
releases the energy
when the terminals are shorted. This energy is not released with the
same properties
that the capacitor but in a similar way that a battery does when the
terminals are
shorted. Thus the time variant that one sees on the energy release is
not the same
as the time varient possesed when delivered to the capacitor but I
could be in error.
I have most of Termans books so if you can point to a section that
confirms your position
and contradicts mine I would apreciate if you would share that section
with me.

Why is the ExB Poynting vector of each wave no longer
proportional to the energy content? Why does the energy
content of the component waves have to change when they
superpose? Where does that energy change go? Do the
necessary joules disappear and/or appear from thin air?

> As a matter of fact
> when superposing two coherent waves (same frequency, fixed phase

That's what I did and the result was 171 joules/sec.
The Poynting vector for each of the two source waves
is 50 joules/sec. Why is the energy content of the
component waves not a meaningful number?

> Summing wave powers could only be done in case of incoherent waves.

No, there is a special equation to be used for summing coherent
waves, i.e. the irradiance equation from optical physics. For
power density:

Ptotal = P1 + P2 + 2*SQRT(P1*P2)cos(A)

where 'A' is the angle between the two E-fields.

> In conclusion, the answer to your question is that the apparent extra 71
> joules/s come front the fact that 100 joules/s taken as reference is a

For every second that passes, 50 + 50 = 100 joules has no
physical meaning? Are you saying that an EM wave is not
associated with ExB joules/sec?

Yes, pity that. Remember that we had a monopolistic telecomms market
until ~1995. I did scavenge a littel copper clad steel (3.2mm) on one
occasion, but most aerial phone cables were HDC.

My article mentions an aluminium clad HT steel fencewire which looks
interesting for antennas, but it does bring the issue of corrosion
resistance connection to aluminium. Unfortunately, this wire is only
available in 1km rolls.

It turns out that HDC is probably the best available wire in Oz (JERD is
a VK5), but gal fencewire or stainless steel are eminently suited to
lossy antennas like TTFD etc.

I do remember Roy discussing the resistivity of rust, but I don't recall
figures... does anyone have any figures for the resistivity of the rust
coating on a rusted steel wire? I guess its permeability is also relevant
to RF resistance.

Owen

Joules do not disappear, they just get distributed over the free space in a non-uniform manner.

In certain regions of the space the two waves add up (apparently creating extra power), in other regions they cancel out (apparently destroying power). The integral of total radiated power does not change.

In your example you considered a location where the two waves have a 45 deg. shift. At another location, where the two waves have a zero deg. shift, you would observe an even higher apparent power creation. Conversely, at locations where the two waves have a 180 deg. shift you would observe absence of power.

The principle causing the apparent power creation at your location is the same principle by which an antenna formed by two stacked dipoles features a gain of up to 3 dB with respect to a single dipole, and can then deliver up to twice the power to a receiver placed at the maximum radiation heading (and zero power at a receiver placed at 90 degrees from that heading). .

> That's what I did and the result was 171 joules/sec.
> The Poynting vector for each of the two source waves
> is 50 joules/sec. Why is the energy content of the
> component waves not a meaningful number?

Each wave produces 50 joules/s when alone. When the two waves are superimposed, each wave produces not only its 50 joules/s but also 35.5 more joules that it "robs" from other regions of the space. If you would plainly sum the power of two components (i.e. 50 + 50), you would neglect the fact that coherent waves necessarily interfere with each other in the space, in constructive or destructive manner depending on the receiver location.

Please re-read my sentence more carefully. My statement was that summing powers (that is. Ptotal = P1 + P2) would only be correct for incoherent waves.

For coherent waves, plainly summing powers would generally be incorrect (apart from one particular phase angle), and one must nstead use the equation you have shown.

> For every second that passes, 50 + 50 = 100 joules has no

I am making various test set ups of different style antennas
which l was a whip style antenna I will procede with testing when
the weather gets in the zero area when I do not expect to venture out
much.
This weeks antenna is a whip style antenna which can be used as a
mobile.
The tests that I anticipate doing is some progressive time cycles of
key down tests all the way up to legal max. This weeks antenna
turned out to have a 250 ohm resistive impedance and I was thinking of
using
a commercial style toroid with multiple taps so I can cover a variety
of antennas with different impedances.(Most are well below 250 ohms)
I have no experience with whip style antennas and was wondering if
there
were any precautions that I should take and whether a single toroid
would be O.K. to use. Some of the antennas will be placed on a fold
over tower
and some will be just above ground level where I have a tube inserted
into the ground
where I can put in different antennas that I have made. Testing will
be done
on bands 160 thru 10M during quiet times to minimize interference.
Wire used on antennas is #18 insulated wire of a household type.
Any pointers would be usefull as I have not performed key down tests
before.
I also intend to have a monitoring camera so I don't go thru to many
8877's

From your original posting, "The following is from an email to which I replied today." There was no indication than anything following that was your reply, and I was curious what your reply was. You're welcome to beat dead horses as much as you like, but that doesn't mean I need to.

Assuming the two "waves" existed independently at some points in space, you'll have to first tell us _exactly_ what was done to combine them into one wave. Right now I'm not accepting that you will be able to combine two independent waves carrying 50 watts each into a single wave carrying more than 100 watts. Thus, it's a "when are you going to stop beating your mother" problem, as posed. There's really nothing interesting except at the point at which the waves combine. But then that's already been explained more than once.

What is the purpose of your 'tests'? That was not made clear in your post.
To just "key-down" using different antennas without a specific purpose makes
it appear that you are testing some sort of impedence-matching device. Don't
forget to Identify yourself with your call sign during the testing.
As for the toroid transformer - multi-tap sounds pretty useful.
I have wound my own toroid transformers, and they worked fine - covered 10m
thru 80meters but I've not used more than 100 watts - I have even used some
of those TV baluns (twin-lead to coax) - and they hold up well at low power.

I have made some different type of antennas and I want to be sure that
they don't melt.
This apparently is not unusual for DIY antennas. Seems like I remember
that you should use
two toroids for top band but I am not sure why. Don't usually use
bands other than
14M Hz up. Read today that a commercial transmission line that
radiates is now available (see
Antenna magazine on line that came out today)Not sure where it is used
tho it would be usefull
for the new amateur antenna design which does not require a ground
plane.

No, I don't believe I've mentioned rust, although I've commented on copper and silver salts a couple of times. I wouldn't try to guess what the resistivity of rust might be, since it would surely vary a great deal with the amount of hydration.

A highly resistive coating won't add appreciable loss, nor will a highly conductive one. There's an in-between range which will. But keep in mind that the skin depth is inversely proportional to the square root of the conductivity, so a thick coating with twice the DC resistivity will increase the RF resistivity only by a factor of about 1.4.

The real problem with thinly plated steel wire is that if and when the coating corrodes off -- or if it's too thin to begin with -- the current ends up flowing in the steel itself. Steel is terribly lossy stuff at RF chiefly because of its permeability, not that its conductivity is all that hot to begin with. Skin depth is inversely proportional to the square root of permeability, so a steel with permeability of 100 has 1/10 the skin depth it otherwise would, resulting in 10 times the RF resistance. If you consider half wavelength antennas at various frequencies all made from the same size wire, you find that the loss gets worse as frequency decreases. So it's often more of a problem on the lower frequency bands.

Some stainless steels are magnetic and some aren't. Magnetic ones are much lossier at RF for the same reason as ordinary steel.

I don't get that magazine, but it sounds like a beverage antenna or some sort of 'traveling-wave' antenna, but I thought they were for receive-only.

Testing that antennas "don't melt" sounds like you're putting us on, trying to get a rise from the conservative hams who believe in not using any more power than is needed for communication. Putting a kilowatt into a mobile whip antenna may get you heard - but won't make you hear any better. You could create a lot of QRM with a combo like that. Antennas are our ears to the world.
Using a whip antenna on a kilowatt rig is analagous to putting on earplugs and using a bullhorn to converse with someone sitting across the table at Thanksgiving dinner - and interfering with everyone else's conversations.
But that's my opinion. You can test your antenna with an antenna analyzer using milliwatts. Throw out those linears!

Reference to a mobile was to illustrate the size of the antenna only.
As you can imagine squashing a 160M antenna in such a small volume
does suggest difficulties !
Best regards

BA984 LHR->TXL 13/June/1998

Certainty level: 100%

In June 1998 I travelled on the above British Airways flight to Berlin with my mother, to visit her family. There were two women in seats 30D/E, about 4/5 rows behind us. It was quite obvious from the torrent of abuse during these flight that these women had been instructed to harass me and attempt to obtain a reaction.

I did manage to record much of the flight, but unfortunately much of the recording is unclear because of high background noise on the aircraft. The following three excerpts from the recording are the best I can do.

The segment at position 11:34 minutes on my recording contains a fairly quiet word "paranoid", followed immediately by a much louder "yeah, he's paranoid, yeah". During the flight the abuse was not sexual, as it so often is elsewhere, but attacking my mental health.

One of the women in seats 30D/E said "paranoid" very clearly towards the end of the flight, but unfortunately I had run out of minidisc space and stopped recording by then. There is absolutely no doubt in my mind that these women were directed to harass me. This harassment happens without fail on British Airways flights; I've been on something like three or four BA flights in the last 5 years and it's happened each time. Presumably this is because of international law which says incidents on aircraft during flight are actionable in the airline's country of origin - so my persecutors want a reaction from me, and they want to see me "done" in the UK where they can influence the justice system.

These incidents never happen on foreign-domiciled carriers.

You are going to need the big toroids for a KW+. 160-10m, as others have pointed out, has trade-offs when done with a single balun of a single type.

The 2.25 (B type, I think--greater cross section area) in. O.D. red material (number not right in front of me) by Amidon has done 1KW 80-10m for me well in the past--but I concentrate on keeping the SWR low. High swr will cause noticeable/damaging heating of the core material--if my experience is any gauge.

For awhile, you could pick up this material on ebay for a song, just did a quick search and didn't turn up any usable material for your needs ... might have to order directly from Amidon.

I picked up a used MFJ tuner at a local ham swap meet. As is my wont, I took off the cover to give it the visual once-over before dumping any 'trons into it. Good thing. About six mounting and/or connection points - screws or nut/bolt combos -- were so loose as to guarantee problems.

It's anybody's guess how long that stuff needed tightening. Was it ever tight? (hint-hint)

"Sal"

PS: The thing works pretty good, overall.

The few MFJ items I have remind me of an old Ford Bronco II that I once owned. It was a piece of junk from day one, extremely useful, and reliable. With a little TLC it ran forever, and was the second best car I ever had. For example, my old MFJ CW audio filter is great, and has given over 20 years of service. But you don't want to look inside at the construction.

I think on this one I will put it on the tower with a tuner and give
it a trial run
with 200 watts. I doubt that I can have a long distance QSO but I can
listen around
for a quiet place to do a low power key down. I will place it
horizontal at
the same time to get an idea of pattern before I invest more time on
that one.
Maybe I need to place a large tuner on the tower and be done with it.
Got two more 160 antennas to make before the snow flies
Thanks for the pointers

Evil old bat in BHS 18/12/98

Certainty level: 40%

Not quite sure how sure I am about this one. I went down to Croydon (Surrey) with my mother to buy her a beret. After doing the shopping, we went to the BHS store restaurant to lunch on fish and chips.

You can guess the rest. Auditory hallucinations my shrink calls them, faithfully recorded on Sony minidisc. Some old cow going on about "see that chap, the one over there, something's wrong with him".

It is quite tiring being attacked by random idiots in the street, or as in this case, by some random, evil old bat in a restaurant. Fortunately it is only a sporadic occurrence. My enemies seem of late reluctant to waste resources in my direction. Should I take this as an insult? Am I not worth the millions of taxpayers money which has been wasted on me? Are the obsessives of MI5 themselves the "nutters" and "really mad" which they accuse me of being? Interestingly this suggestion as to the psychological profiles of Security Service personnel has been made by others... it does lead one to wonder, doesn't it?

Source record: 33695

The 'best' wire for long antennas is whatever you happen to have
the most of that will support it's own weight. After that, it's more
a matter of what color insulation you think is nice. And after that,
it's whatever you can convince yourself that you can afford. Have
several pieces of different wire size/type? If they will support
their weight, splice the @#$ things! Paint it all pink. Pink works
very well for antennas.

Ravenscourt Park 20/3/99

Certainty level: 70%

On Saturday I went to Hammersmith, specifically Ravenscourt Park. There had recently been a resurgence of persecution activity, following the Capital spams. I went to the cafe in the park and had a cup of coffee outside, with my mother. As I went inside the cafe to return the cups, a woman shouted a sexual obscenity (not present on this audio file - don't ask), and she said loudly "something's wrong with him". You can just about hear it in the audio file; listen very carefully, several times; it is distinguishable.

Much less subtle is the male voice shouting "take care he's a nutter" immediately after the woman's voice. As on the other recordings there's a lot of noise, but what the people say can be clearly heard.

Given that I take medication and look and behave quite sanely, and that there had been increased abuse over the last couple of weeks, it seems pretty unlikely that this incident was just spontaneous.... of course, you couldn't prove otherwise, but then that's the way MI5 mean their abuse to look.

Battersea Library 29/3/99

Certainty level: 60%

This one is quite dull. During the month of March 1999, MI5 made another determined attempt to "get" me, substantially through radio programmes, through Jon Snow on Channel Four News, and through abuse in public, of which this is one example.

Recorded on my minidisc-walkman on Monday 29 March 1999, this audio file consists of two girls talking. One says to the other, "he's got something wrong with him." The usual words. How many millions a year do the Security Service waste on this? But they've denied it - how silly of me to forget. And they're not liars either, are they?

> nature of the equations that you use.

The last term in the following power density equation
is known as the "interference term". If it is positive,
the interference is constructive. If it is negative,
the interference is destructive.

Ptotal = P1 + P2 + 2*SQRT(P1*P2)cos(A)

Ptotal = 50w + 50w + 2*SQRT(2500)cos(45)

Ptotal = 100w + 100w(0.7071) = 170.71w

The interference term is 70.71 watts of constructive
interference indicating that there must exist 70.71 watts
of destructive interference elsewhere in the system.
If the constructive interference happens at an impedance
discontinuity in a transmission line in the direction of
the load then there must be an equal magnitude of
destructive interference toward the source.

My point exactly! The same thing is true when it happens
in a transmission line at a Z0-match point. The region of
constructive interference toward the load (forward energy
wave) "robs" energy from the region of destructive
interference toward the source (reflected energy waves).
That's how antenna tuners work.

The posting was my reply to that original email.

> Right now I'm not accepting that you will be able
> to combine two independent waves carrying 50 watts each into a single
> wave carrying more than 100 watts.

It happens all the time at a Z0-match in a transmission
line. Please reference Dr. Best's article in the Nov/Dec
2001 QEX. He combines a 75 joule/sec wave with an 8.33
joule/sec wave to get a 133.33 joule/sec wave.

Ptotal = 75 + 8.33 + 2*SQRT(75*8.33) = 133.33 joules/sec

Dr. Best's article was the first time I had ever seen
the power density irradiance equations from the field
of optical physics used on RF waves.

Royal Festival Hall 15/4/99

Certainty level: 100%

Another "day in the life of", this one. January and February were quiet; in March it all started again; by the middle of April the resurgence of abuse had been going on for over a month. And this, with 100% certainty, is one manifestation of the abuse.

On Thursday 15 April 1999, 1pm lunchtime, I was at the booking office at the Royal Festival Hall near Waterloo Station in London, buying a ticket for a friend. A woman was at the counter next to me. She said;

"it would kill it, you know, it would just be overkill...
.. they can't stop can they"

It was obvious to everyone, the ticket agents included, that her comments were directed at me, and that "they" (ie. MI5) were "killing" me.

I've heard similar things said at various other times, but rarely have their intentions been expressed as clearly as this. The woman also expressed the obsessive nature of MI5's preoccupation with me, by saying, "they can't stop can they".

I share Tom B's suspicions. Since Cecil's analysis is leading to physical absurdities such as "watts of destructive interference" and vagueries such as "elsewhere in the system", it means that something is wrong. It could be either in his statement of the problem, the suitability of his chosen method of analysis, or the way Cecil is applying that method; or any combination of the above.

Either way, it is Cecil's tarbaby, and nobody else needs to get stuck to it.

The rest of us can continue to use the methods that have existed for a hundred years to account for the voltages, currents and phases at any location along a transmission line, and at any moment in time.

Balham - LT bus (8/July/1999)

Certainty level: 90%

I am very sure about this one. I got back from holidays on Wednesday. There were two incidents, both on the tube, on the way back from the airport. There was a further incident the following day, Thursday, on the bus (the 155 I think) in Balham, where two girls started spouting abuse about "crazy", etc. Naturally I had my minidisc with me and was able to record their words.

The cynical reader might think my demeanour or behaviour had given rise to the taunts of "crazy" recorded above. But I assure you my behaviour on the bus would not have made anyone think I was ill; and the taunts the previous day were the same sexual words as previously; so I'm quite sure that these incidents are either deliberately staged, or indicative of an overall high level of awareness among the London public, particularly in the part of London where I live.

Clapham South (17/Feb/2000)

Certainty level: 100%

In February 2000, MI5's hate campaign against me was in full swing. They sent people into the road where I live in south London, to swear at me and abuse me as I was leaving or returning home. One such instance is recorded on the above audio file.

On Thursday 17 February 2000, I had just left my home, en route for Croydon, when two youths approached, going in the other direction. One of them said with a smile on his face something which I didn't recognize, and still don't understand despite it being on this audio clip. His demeanour made it clear his statement was directed at me. I coughed, and in response to that, he continued his insult, calling me a "wanker", which is very clearly recorded on this audio clip.

Two days later, in the very early morning of Sunday 20 February 2000, MI5 inflicted another insult against me just outside my house, when, returning from Croydon, two youths approached (MI5 agents always go in packs of at least two - they're too cowardly to go anywhere on their own) and one of them said quietly and bitterly to the other that "he's shitty, very shitty".

It is still comparatively rare for MI5 to send people to my house, or to my road, to harass me. Usually they know where I'm going to, since they have bugs on my phone and in each room of my house; and they send people to that location, or on the train or tube getting there.

What you must understand is t5he circuit that constitutes a
capacitor part of which is a resister that is seen in parallel.
So yes, a portion of energy can bypass the capacitor.
However the time varient that one must measure is at best,
a superinposed expellation of energy from the capacitor
which changes the original time varient required for radiation.
Cecil makes the point he can measure the current
along the radiator, but in fact he has a measuring problem
by what he is using to measure current with respect to time.

You can come up with a lot simpler example that at first might look like a paradox. Consider two DC current sources of 1 amp each. Each current source will deliver 50 W to a 50 Ohm resistor. Now connect the two current sources in parallel, and the resultant 2 amps will deliver 200W to the same 50 Ohm resistor. There is nothing wrong here.

Clapham Junction (6/May/2000)

Certainty level: 60%

On Saturday 6 May 2000, I was in Clapham Junction, shopping and visiting the library. At precisely 12:29pm, the above audio clip was recorded, in front of Arding and Hobbs department store. One girl was saying to her friend,

"He's a homosexual, they can say whatever they want."

There are several reasons why I think this comment might be about me. Firstly, temporal proximity to other such incidents. The persecution had restarted about two to three days before this clip was recorded. Cause of restart unknown. Personally I think it's because I was going on holiday to France the following Monday - MI5 do like to take holidays abroad at the taxpayer's expense, and inventing reasons to resurrect their hate campaign just before I go on holiday is something they've done before.

Secondly, although I am not gay, they have used such references against me before. At Oxford Computer Group in 1994, manager Steve Mitchell simultaneously abused me and another employee but saying we were "of a similar bent". Such insults show latent or quite overt homosexuality on the part of the abuser.

Thirdly, the sort of people who abuse on the basis of mental illness are the same people who abuse others on the basis of sexuality, race, religion, etc. If they can abuse a disabled man, then they will surely do so based on the other criteria mentioned.

There is still some room for doubt, though, which is why I have assigned this recording a certainty level of only slightly above evens. But "they can say whatever they want" is what gives the game away; they just choose a differentiating feature on which to base their abuse; and if one such feature gets too boring ("we've called him a nutter for the last ten years so now we'll call him something else") then they invent a different lie to throw at me.

yes, lets say source S1 supplies a voltage V1 into a load L1, where L1 is a pure 50 Ohm resistance.

>
> Wave#2: V = 50v at 45 deg, I = 1.0a at 45 deg, P = 50 joules/sec

Source S2 supplies a voltage V2 puts into a load L2, where L2 is a pure 50 Ohm resistance.

> These two waves superpose to V = 92.38v and I = 1.85a
> Note: P = 171 joules/sec

You have changed the circuit.

Source S1 is no longer connected to a load L1 consisting of a 50 Ohm load. It is connected to a load L3, consisting of a pure resistance in series with a voltage source.

Since you have changed the circuit source 1 is connected to, you should not be surprised it supplies a different power.

Move the phase difference to 180 degrees, and source S1 would supply no power at all.

> *During each second*, Wave#1 supplies 50 joules of energy and

> coming from?

35.5 J/s (Watts) comes from the source S1 and 35.5 J/s (Watts) comes from the source S2. It's different to the first case, as they are connected to a different circuit.

You can do the same with DC - you don't need to use AC at all. Put a 50 V battery in series with the pure 50 Ohm load and it supplies 50 W. Put

it in series with another load, consisting of a 50 Ohm voltage source in series with a 50 Ohm load, and it is no surprise it delivers a different power. Depending on what way you connect the two batteries, the current would be 0 A or 4 A, and so the power 0 or 200W.

Of course, the sources simply deliver the extra power.
But in our previous examples, the source is nowhere around
the point of interference and therefore cannot be the source
of the extra power. Away from any source, the energy required
by constructive interference *always* comes from destructive
interference somewhere else.

In a Z0-matched transmission line with reflections, the
constructive interference is toward the load at the Z0-match
point and the destructive interference is toward the source
at the Z0-match point.

An understanding of the constructive and destructive
interference at a Z0-match point is a necessary and
sufficient condition for understanding where the
reflected energy goes which is the whole purpose
of this thread.

In typical Cecil fashion, you trimmed out the only part I really cared about having you answer: "Assuming the two "waves" existed independently at some points in space, you'll have to first tell us _exactly_ what was done to combine them into one wave." Depending on how _I_ do that, I can get various answers, since some power goes elsewhere in some of the methods, but I _never_ get more power out of a steady-state system than I put in. Barring stupid math mistakes, anyway.

Adios,
Tom

Do you think Eugene Hecht of "Optics" fame is wrong?
The unit of irradiance is "watts per unit area" and is
NOT a "physical absurdity". Hecht uses "watts per unit
area of destructive interference" quite often in his
classic textbook. He says the spacial average of all
interference must be zero so that the watts per unit
area of constructive interference must be balanced by
the watts per unit area of destructive interference
elsewhere in order to satisfy the conservation of
energy principle.

Nothing is wrong, Ian, you are simply ignorant. I suggest
you read the chapter on interference in "Optics" and try
to comprehend it. It might do you good to learn something new.

> Either way, it is Cecil's tarbaby, and nobody else needs to get stuck to
> it.

By all means don't try to learn and understand anything new.
Newsgroup gurus apparently already know all there is to know
and are therefore incapable of additional learning.

> The rest of us can continue to use the methods that have existed for a
> hundred years to account for the voltages, currents and phases at any
> location along a transmission line, and at any moment in time.

And that is exactly why you don't understand reflected energy.
An understanding of of interference can be had from a voltage
analysis but you obviously have never performed such. It is
common knowledge that V1^2+V2^2 is not equal to (V1+V2)^2.
The question as to why they are not equal has been avoided
even though it is easy to answer. If (V1+V2)^2 > V1^2+V2^2
then the superposition of voltages has resulted in constructive
interference. If (V1+V2)^2 < V1^2+V2^2 then the superposition
of voltages has resulted in destructive interference. Away
from any source, constructive interference must always equal
destructive interference to avoid violating the conservation
of energy principle. At a Z0-match point, the reflected energy
is redistributed back toward the load by constructive interference.
An equal magnitude of destructive interference occurs toward

the source thus eliminating reflected energy toward the source.
It is the same way that thin-film non-reflective glass works.

Source record: 33719

My neighborhood is loaded with some kind of electrical noise which makes working 160 & 75 meters difficult. I have tried to locate the source but have come up empty at this point. It appears to be something other than power line noise which may mean its coming from someones house.

I was hoping the solution to the problem was to build a low noise receiving loop antenna.

Well, the noise is mostly gone.....but so are the signals.....even when I use a preamp.

I have tried an ICE 75 meter preamp and a KD9SV 160/75 meter preamp.

Still the noise is gone but the signals are really weak, if I hear anything at all.

Not sure what if anything I did is wrong or if I am expecting too much from this loop or the preamps don't have enough gain to make this work.

Anyone familiar enough with receiving loops to be able to assist me in figuring out whats wrong here?

TIA

Tony

The physics of EM radiation.

As an example, consider an array comprised of two, identical radiators on the same vertical axis, in the same physical orientation, with a vertical separation of 1 wavelength, each driven with equal r-f power and relative phase by the same r-f source.

The fields from the two radiators are generated and radiated separately, but once well past the near-field boundary of the array, the EM field existing at every point in free space will be the vector sum of those separate fields.

When the net field at the radiation peak of the array is measured in the far field, there will be no way to determine from that measurement whether the field was generated using a single radiator with X power input, or the described 2-element array having about 1/2 that power input.

Hiding behind authority again, Cecil? Using a few carefully edited
quotes from Hecht doesn't prove anything. Ian hit the nail on the
head: Vague philosophical arguments using second and third order
abstractions that you can't prove to have any connection to reality
aren't going to convince anyone.

So in the limit, as the number of radiators is increased to infinity,
the amount of power it would take to produce the measured sum would
go to zero. Nice logic.

Hi Dave,

Your analysis, or critique rather, has been misdirected. In fact, everyone has been suckered. Not unusual given the problem was crafted to be disingenuous. It is, after all, this group's form of "Three Card Monte." Can you pick the card that is the one-eyed Jack?

With a little re-ordering here....

On Sat, 17 Nov 2007 16:08:04 +0000, Dave <nowhere@nowhere.com> wrote:

>> Wave#3 = Wave#1 superposed with Wave#2
Wave#3 is the only thing real here.

>> These two waves superpose to V = 92.38v and I = 1.85a
>> Note: P = 171 joules/sec
Superposition is a process that gives us a solution to a system that exists, not a figurative one. However, the process of superposition requires the suspension of reality to perform computation, and to render the solution that is real.

>yes, lets say source S1 supplies a voltage V1 into a load L1, where L1
>is a pure 50 Ohm resistance.
Dave, herein lies everyone's presumption, and one that has been "suggested" originally. What you "interpret" does not exist independently. In fact, S1 has no independent existence (neither does the other source). This is the artificial contrivance of partially solving a superposition problem.

Let's simply look at these "suggestions:"
>> Wave#1: V = 50v at 0 deg, I = 1.0a at 0 deg, P = 50 joules/sec
In the reality of two waves, this artificial condition is arrived at only through removing the second wave from the reality. And like wise:
>>
>> Wave#2: V = 50v at 45 deg, I = 1.0a at 45 deg, P = 50 joules/sec
In the reality of two waves, this artificial condition is arrived at only through removing the first wave from the reality.

Neither of these artificial conditions actually exist in the reality of superposed waves, and that is the con. The group has been fixated on the separate artificial environments with their partial solutions as though they actually exist independent of the reality of the superposed, complete solution.

>You have changed the circuit.

Of course he has. That is the allowed method of computing
superposition (he has in fact not done the full method of
superposition analysis - but that is immaterial to the discussion
except only to note that Cecil's posts are often rife with error).

The egregious error is found here:
>> *During each second*, Wave#1 supplies 50 joules of energy
Wave #1 is not independent in reality, so the statement is wrong. What
is provided (50 joules) is only a partial solution in the method of
computing the superposition which for that computation, suspends
reality to examine the separate constituents in an artificial
environment.

But these are not "sources" per se, they are EM
waves with a fixed constant energy content. EM waves
simply cannot, willy-nilly, increase their energy
content. The actual source could conceivably be
light-years away so it would take light-years to
increase the energy content of the EM waves.

So please tell us how a 50 watts/unit-area wave can
increase its energy content to 85.5 watts/unit-area
while being light-years away from any source.

Crescent Grove, Clapham Common (2/Dec/2000)

Certainty level: 100%

This is one of those clips where I am absolutely, 100% certain it's inflicted by MI5 on me, because of background, context. On Saturday 2 December 2000, I was walking from my home to a pub on Clapham Common, and on the way was in proximity to a group of three English youths who were walking the other way. They turned from the main road into a private estate called Crescent Grove. Here is what they said;

(first youth) "He masturbates!"
(his mate responds) "Yeah, he masturbates!"
(and again) "Thief!"

There is a lot of context associated with this incident, which I will now relate.

Firstly, the verbal sexual abuse is a popular one with MI5, and as a statement about me is currently mostly in their imaginations. The accusation has to be seen relative to MI5's persecutory actions in late November and early December 2000, and in fact for some months leading up to this. Their relevant activities in June 2000 are documented in a message in this evidence item; following from that, they sent someone to simulate an act in front of my window, which was captured on film.

It is the publication of the video of their agent performing the act on himself which caused MI5 to restart this thread of harassment in the first few days of December 2000. But there are some subtleties; I uploaded the digitised video to this website on 26/November/2000; but I did not announce its existence on the newsgroups until Sunday 3/December/2000. These youths' slur was made the previous day, on Saturday 2/Dec. That tells us quite a lot. According to my website logs, there were no accesses to the video file before Sunday 3/Dec. So why did MI5 restart this particular thread of abuse, before their agent's activities were published on the newsgroup? The conclusion we reach is that they were watching my internet connection, either decoding the telephone line, or at the ISP; and/or they may be able to physically see what is on my notebook computer's screen, from RF transmissions from its VGA circuitry. I do not know whether the latter is technically feasible, but the former certainly is, and I have known for years that MI5 bugs my internet activities and phone calls. It is from their observation of my internet connection that they were able to tell, without accessing the video file over the net, that it was of their agent in a compromising position; and it was from that observation that their shouted slur on 2/Dec emanates.

The second accusation, "Thief!", is even more interesting. It relates to occurrences from June of 2000, some six months before these youths threw the word at me. It shows just how wide in reach geographically and temporally the MI5 persecution is; they react to something which happened half a year previously.

In the first half of 2000, MI5 made a determined assault on my friendships. In one particular case, that of A. whom I had known for virtually all my life, they partly succeeded. This person made pointed references to me which made it clear he knew what was happening; at one point he started asking "do you know anything about the FBI and the CIA". In June 2000, we went to see a film in the West End. I paid for both of us, and then asked him to return what I had paid for his ticket, some £7.50. He was reluctant to do so. Eventually he returned £5, settling for the lesser gain of £2.50.

I did not call him a thief to his face, but I may have spoken the word while I was at home, either conscious or in my sleep. MI5 have very tight control over everything I do and say in my home through their bugs; if I say anything against someone in "their" camp, they turn round the accusation against me. So, from the fact that A. tried to garner a few pounds at my expense, MI5 create the accusation, six months later..... "thief!".

They were confined to a transmission line. Coherent
waves traveling in the same direction in a transmission
line are forced to also be collinear. Unlike space, a
transmission line forces collinearity upon the EM waves.
But the same thing happens at a 1/4WL thin-film non-
reflective coating on glass. Assuming one brings the
Poynting vectors into collinearity, one can see what
is happening at http://www.w5dxp.com/thinfilm.gig

Hi Tony,

There is no such thing as a Low Noise antenna (loop or otherwise).

Given that what you build is deaf, that should be a reality check of
this presumed quality of the antenna.

Well, actually, you built it wrong. However, building it right stands
only a partial chance of lowering noise, and not because the antenna
has some remarkable quality that is not otherwise found in the plug
ordinary dipole. In that sense, the reduction of noise would only
follow turning the dipole (or loop, same thing) until the source of
that noise fell into a null. This is the conventional method of
employing a "Low Noise" antenna.

Let me guess. It is a shielded loop. You forgot to leave a gap in
the shield.

It seems strange to me that people who know that antenna gain in one direction comes at the expense of gain in another direction cannot carry that concept over to transmission lines. Constructive interference in one direction means destructive interference in another direction. That's what creates the radiation pattern for antennas. It is also exactly the same thing that routes energy toward the antenna instead of toward the source in a Z0-matched transmission line.

Hi All,

It is with some reflected amusement that I pause here to relate a
story. I was once tasked to calibrate an HP precision current source.
I had faithfully connected my standard shunt and voltmeter to do just
this, and the source performed exactly as specified (HP equipment that
wasn't broke, always did). I then disconnected the leads and was
immediately bit. The source performed exactly as specified!

Hi Tony,

It is working perfectly! It is working exactly as it was constructed.

You got your plans from the wrong source (or misread them, or failed
to follow directions).

There are several ways to construct one correctly, so I won't go into
those variations. There is probably a fix to the one you have, but
that is shooting in the dark.

Let's simply investigate the quality you seek. Low Noise comes only
from the antenna's quality of yielding the best dipole performance
possible under the circumstances. As these circumstances often
involve use in the low frequencies, the traditional high elevation
long-wire dipole is usually not an option. Further, if it is, it
rarely allows for rotation. What is usually within the user's skill
or available space renders a dipole that suffers from the proximity of
"things." These "things" disrupt the balance, and hence the
directionality of the dipole; thus noise sensitivity rises (noise
fills in through what should have been nulls in the dipole pattern).
The user still cannot turn the dipole and thus the long-wire in the
garden is a mediocre performer at best, and is usually a
disappointment all around.

Enter the loop.

The traditional loop for low frequency use is in fact quite small. By
being small it suffers less in relation to the proximity of "things."
This, of course, is if you erect it in the same place as that
long-wire disappointment you tugged down. That is, the loop improves
only in comparison; fortunately, it also brings the virtue of being
rotatable. That would be enough, but the snake oil salesmen like to
guild the Lily.

Enter the shielded loop.

The shielded loop solves a problem, certainly. That is the problem of
balance. However, if you use careful crafting of a simple loop, you

don't have any problem to solve.

There are many other details to sort out. That can be left to other correspondence.

As the number of radiators in a given array never can reach infinity, neither will the input power for a given peak ERP from that array ever go to zero. Obviously there are practical limits as well.

But this does not change the realities that...

1) other things equal, the greater the number of discrete radiators in an array, the less input power is needed for that array to produce a given peak ERP, and

2) the peak free-space, far field produced by a given ERP is the same for all combinations of antenna gain and antenna input power producing that ERP.

This has been proven in commercial FM and TV broadcast systems for many decades.

Richard, I use a vertical antenna, for transmitting its great, does a fine job, but for receive, with the noise in the neighborhood, its not the best option. I have tried to use an ANC-4 noise reducer but the noise isn't reduced enough to hear the weaker signals.

So, what to do, I followed the instructions for building the loop from W2YR and KN4LF and from this link
http://www.hard-core-dx.com/nordicdx/antenna/loop/coaxloop.html

As I wrote previous I have 2 good preamps but the signals are still very weak.

Have you ever built one of these?

If so, did you experience the same problem?

I don't have room for a beverage but if I am unable to solve this loop issue I will probably have to consider a K9AY array which will force me to move other antennas around on my 1/3rd of an acre.

Yes, therefore the additional energy is supplied from the source (ultimately
from the mains installation). You know this already as you say, "at first it
seems like a paradox". I agree, it does. It is a good example of a false
paradox ;-)

But the situation at hand is a transmission line where it is a given that
the sources cannot adjust the power they deliver. I believe in the case at
hand (a transmission line far removed from the source) that it is possible
for there to be a plus power differential from the sum of the source powers
at any given segment as long as there is equal power subtracted at another
location. The law of conservation of energy still holds true for the system
as a whole. The same thing happens with anrennas so why not transmission

lines?

Hi Tony,

Leaving that aside for others to comment....

>So, what to do, I followed the instructions for building the loop from W2YR
>and KN4LF and from this link
>http://www.hard-core-dx.com/nordicdx/antenna/loop/coaxloop.html

There is a world of opportunity in making a mistake with this monster.
It goes a long way to do something difficult that could be done vastly
easier.

>As I wrote previous I have 2 good preamps but the signals are still very
>weak.

You state that there is no gap. The page you supply clearly shows
gaps at the top of the two loops. Anything you hear is a function of
the poor shielding. By your description of your construction, you
shouldn't be able to hear anything at all!

>Have you ever built one of these?

No, not one of these (there are too many frogs to kiss them all).

>I don't have room for a beverage but if I am unable to solve this loop issue
>I will probably have to consider a K9AY array which will force me to move
>other antennas around on my 1/3rd of an acre.

A solution is vastly simpler than that - and you can still build a
loop. Google for more designs and submit them here for review (the
one you provided rates low on the sanity scale).

Because I don't have to prove you wrong, Cecil, you have to prove yourself right. So far, you've given us nothing but a few untestable assumptions and little else. A series of declarative sentences and obscure analogies does not a theory make. When you can work out 1. A logical framework, using vector calculus, in order to show us, logically, why we should pay attention to you, and 2. A series of easily replicated experiments that you've performed, and we can perform in turn, to see how well your ideas are supported by reality, then, maybe we should give you a hearing, but a series of unsupported statements followed by a barrage of objection stoppers just isn't good enough. This may be fun for you, but, for anyone dealing with you, it's just a waste of time.

Cross-posted to: alt.tv.reality,alt.music.canada,rec.crafts.textiles.sewing,rec.outdoors.fishing.fly.tying,rec.radio.amateur.antenna

Virgin Radio-Jon Holmes (4-5/Jan/2002)

Here are two segments from Virgin FM, one on Friday, the other on Saturday,
both from the Jon Holmes evening show.

Certainty level: 80%

In early January 2002 I listened for the first time in some months to Virgin Radio,
specifically to the Jon Holmes evening show on Friday 4 January 2002. They promptly
attacked me verbally. Again, context is relevant. There are three instances in the
space of two minutes on this extract;

00:18 "are you lying?"
00:22 "it's not fair"
01:24 "everyone at the amateur c+ turbo programmers club found it hilarious"

The first phrase is a straight slander. MI5 were trying to portray me as a liar at
around this time; I have other audio with the same accusation. "are you lying?";
unsophisticated.

It's closely followed by the words "it's not fair". Note carefully the way he says it,
quickly, as if to deny what he says. The phrase "not fair" was first created by OCTS MD
H S.-W. in Nov/1992, and picked up on my first visit to hospital soon after
"they should have paid your fare").
Again, unsophisticated parrotting of a key phrase.

The third phrase is explicable through contemporaneous context. That morning I had
phoned about a C++ course. "c+ turbo programmers club"... again, somewhat brazen
we're-listening-to-what-he-says-on-the-phone, and he-can't-prove-it. Something got lost
in translation from MI5's watchers to Virgin, because "c+ turbo" means nothing.... there
is no C+ turbo language, only C++, of which Turbo C++ is one implementation.

Certainty level: 80%

I wasn't entirely convinced from Friday's programme, but the following evening's
show confirmed it. It contained a number of references to my condition, of which the
following excerpt is one such;

00:09 "I'm not well, and no-one cares"
00:24 "my voice sounds all funny"
01:01 "do you mean people that aren't mad"
01:05 "medical problem is it"

"I'm not well" doesn't mean he has a cold; it means he is being sarcastic about my
mental illness. "my voice sounds all funny" refers to the change in nature of my
voice when acute illness hits. "do you mean people that aren't mad" is obvious.
"medical problem is it"..... rubbing salt into the wound.

Your example, though correct, has little to do with the case being discussed.

In your example it is true that power varies depending on what way you connect the two batteries, but in all cases the total power dissipated in the loads remains equal to the total power delivered by the sources.

In the case being discussed instead the power dissipated in the load varies with NO CHANGE in total power delivered by the sources.

Hello Richard, with all due respect to your background on this, which is much much greater than mine, I do have fundamental concepts that were modeled in my mind many years ago at the University and even to some extent in high school. No need to try to align me with other posters who I may agree with, as you would political parties. Nobody is running for office here. I tend to see no violations of physical laws provided they are held true for the system as a whole, *provided you have defined a closed system*, and he has. That is the way laws of science behave.

I think you are describing a scenario where, with the loop+preamp, the receiver system is limited by internal noise rather than external noise.

So, it is a two band design, and that complicates matters somewhat.

Just concentrating on the 160m loop...

My calcs are that the 160m loop alone, tuned for zero series reactance (should need ~90pF) and loaded with 50 ohms should have equivalent gain of around -47dBi.

You would have to consider the preamp NF and gain and receiver NF to evaluate the system noise floor, and you haven't given those details (though they may be implied... but I am not familiar with the preamp you are using).

Without using a preamp, the external noise (based on ITU-R P.372-8 Residiential man made noise) with this loop ought be of about the same magnitude as the internal noise of a good transceiver, give or take. For a preamp to improve the situation, it would need a NF significantly better than the transceiver and sufficient gain to overcome the transceiver noise.

no way. Prove there is no change in the power delivered by the sources.

I see Cecil is still superposing his waves of average power.

I have an example that's more fun yet.

Take a 10 volt source and connect it through a 10 ohm resistor to another 10 volt source. The positive terminals of the sources are connected to the ends of the resistor, and the negative terminals are connected together -- "grounded", if you prefer. Turn on one source, leaving the other off. (An "off" voltage source is a short circuit.) Result: 10 watts of dissipation in the resistor. Turn off the first source and turn on the second. Result: 10 watts of dissipation in the resistor. Now turn both sources on. Result: An exercise for the reader.

This is a linear circuit for which superposition holds.

A largely rambling response. It describes, but doesn't actually
answer how
"a plus power differential from the sum of
the source powers at any given segment"
is so overly elaborate to be a fundamental concept supporting an
erroneous speculation Cecil is offering.

If you in fact think that the issue of accepting a broken argument is
on par with High School homecoming elections, that is not the race I
am competing in. If you want to stick with a technical issue in a
technical forum, then strict language and solid logic is still a
requirement.

No matter how you combine two waves in space or a transmission line in such a way that they add, the process will result in other regions in which they cancel, and vice-versa. The result is the correct net power in the *whole system*. Long ago I issued a challenge for someone to describe a system for which this isn't true, and re-issued it recently. No takers.

Attempting to apply the law of conservation of energy, or anything else, to one region while ignoring the others is certain to lead to bogus conclusions, as we've seen over and over.

What you've done is to build a truly shielded loop. The notion that a shield somehow blocks the electric field and lets the magnetic field through is a folk tale -- an intact shield like the one you built blocks both electric and magnetic fields. (Good thing, too, or else coax cable wouldn't do its job.) You've just done an experiment that proves it.

The gap in a so-called "shielded loop" provides a path for current outside the "shield" to get inside. The net result is that the outside of the "shield" is just an ordinary loop antenna, and the gap acts like a feedpoint to get the current inside where it can get to the receiver. It responds to normal electric and magnetic fields exactly like an unshielded loop. What the "shield" buys you is improved balance, which helps prevent the feedline from becoming part of the antenna and picking up local noise which you can null out if balance is good.

I did do a search for loops of this type and basically they are all the same.

I have been told Wellbrook makes good loops, but I don't like the idea of spending $300-$500 for one at this point.

Roy, I don't fully understand why you made this response to me.
You mentionI built a truly shielded loop. How so? I did exactly what the
directions called for including having a gap.

If these loops are a folk tale, other than using a beverage which I don't
have the room for, how am I going to reduce the noise enough to be able to
woprk 160 and 75 meters effectively?

There are many sources of non-Copperweld-brand stranded copper-clad-steel wires from the ham retailers, e.g. www.therfc.com, www.thewireman.com, etc. It's a joy to use and handles more like aircraft cable than solid springs.

Some insist it has to really be Copperweld brand to be good but my standards aren't so high. Besides Copperweld-brand stuff seems to be conspicuously out of stock at all the ham retail shops, and when I inquire about it they tell me that they don't ever expect to get it again.

Tim.

In a closed system, this is so un-elaborate that I can even take this down
to grade school artithmetic, Richard. When I add all of the power
differentials from source power with a plus sign in front of them, to the

power differentials from source power with a negative sign in front of them, the sum must be zero. We're talking about power so I don't even have to go to high school to learn about summing vectors.

What am I missing here?

Then I am sure you will agree that using terms like "taking Cecil's sucker bait" is not the type of "strict language" and "solid logic" appropriate in a technical forum.

Ok, I can't work with specs like "Noise figure is quite low and the design appears to have no vices." I am not saying it is bad, it just doesn't say anything meaninful... well to me anyway.

Still no info on the transceiver, but lets guess it has a NF=8dB.

Transceiver + preamp has a NF of 2dB, which suggests an equivalent noise floor of about -139dBm (2kHz bandwidth).... provided that the preamp doesn't generate internal noise due to IMD and which would not be captured in the 1.8dB spec NF.

ITU-R P.372-8 suggests ambient noise on 1.8MHz in Residential locality should be about -75dBm+AvgAntGain or about -122dBm, so you should get noticeably more noise (~17dB) from the loop than from a dummy load. That would mean the configuration should deliver almost as good a S/N ratio as possible... even though the S meter reading might be shy.

Again, I am talking about the 160m loop alone. You can't diagnose this easily with the two loops in parallel.

Owen

Yes, at least someone understands. The "plus power" is
needed by constructive interference. The "power subtracted"
is given up by destructive interference somewhere else.
Apparently, none of the gurus on this newsgroup have ever
considered where the "plus power" comes from while
belittling anyone who wonders where it comes from.

I am using a heavily modified Drake R-4c receiver. Sherwood mods.
And I at this point I only built the 80 meter loop as I wanted to make sure
it worked on 80 before I went and built one for 160.

I don't think ITU-R P.372-8 had my neighborhood in mind when it was
composed.

S-9 on this receiver is about the minimum on 160 and S-7 is the minimum on
75.

Much of the time its higher and a royal pain in the arse.

Well, for one powers do not add, just energies.

The point of the matter is that the method of Superposition does not
reveal the nature of reality by parts, only by its whole.
Superposition is an artifice, a method, where reality is suspended
pending completing the analysis. To stop in the middle and proclaim a
new reality is a fraud. But then I've already explained this
elsewhere (did you follow that lead?).

>> If you in fact think that the issue of accepting a broken argument is

>Then I am sure you will agree that using terms like "taking Cecil's sucker
>bait" is not the type of "strict language" and "solid logic" appropriate in
>a technical forum.

In fact, it is in the strictest language par excellence! Strict
allows for no wiggle room, nothing nebulous. You completely
understood what it meant and technical forums are assaulted with a lot
of bankrupt theories- sometimes innocently offered, but not in this
case. You might complain of style, but not substance.

If you want it in another style, I could easily comply, but evoke
groans from many following this (and more complaints of style). On
the other hand, the substance of the issue is that the origin of this

thread is a patchwork of unremittingly failed logic that many here have accepted as a point from which to argue. Tom has already identified it in the class of argument "Have you stopped beating your mother?" The crew here picks the theme up and starts asking for definitions of mother, beating, "when does stop actually occur?", and the rest. It does have its amusement, however. ;-)

Anything for which you cannot provide a technical answer
appears to you to be "sucker bait". No underlying premise
is broken. EM waves interacting at a Z0-match simply obey
the laws of physics including the conservation of energy
principle. For every packet of additional energy needed
for constructive interference to occur, a packet of energy
becomes available from destructive interference.

Tony,

A few questions:

1. With a 50 load on the preamp input, when tuned to a quiet spot in the band, RF gain full, preamps on, telephony bandwidth, does the S meter deflect at all?

2. If no s meter deflection, note the receiver audio output voltage.

3. With the loop connected on the preamp input, when tuned to a quiet spot in the band, RF gain full, preamps on, telephony bandwidth, does the S meter deflect at all?

4. If no s meter deflection, note the receiver audio output voltage.

5. What is the ratio of the voltage at 4 to the voltage at 3? If it is more than about 3:1, you have achieved nearly as good a S/N ratio as is possible.

> no way. Prove there is no change in the power delivered by the sources.

Making reference to the case under discussion (Wave#1 produces 50 joules/s at the receiver when alone, and so does Wave#2 when alone), imagine that the two waves are generated by two remote transmitters (+antennas) and that you measure the power of the two superimposed waves on a receiver (+antenna) that you can move in the space as you like.

If you put your receiver/antenna in a point where the two waves have equal amplitude and opposite phase, your receiver will measure zero joules/s.

If you instead put your receiver/antenna in a point where the two waves have equal amplitude and same phase, your receiver will measure 200 joules/s (i.e. four times the power produced by each wave alone, not just two times).

Finally, if you put your receiver in a point where the two waves have equal amplitude and a 45 deg. shift (as in the proposed case), your receiver will measure 171 joules/s (still more than twice the power produced by each wave alone).

Moving your receiver here and there will obviously cause no change in the power delivered by the two remote transmitters.

The trick is due to the fact that the two waves interfere each other in constructive or destructive manner depending on the particular receive point. So, in the "lucky" points you get some extra power, which is however compensated for by the power loss occurring at the "unlucky" points.

The original question is deceiving, because it attracts the reader's attention on just one particular point of the space, where energy can unexplicably appear to be created or destroyed. But instead considering the power distribution over the whole space, the mistery disappears.

-sigh-

Tony, if "loops don't work" is the only message you've gotten to this
point, it is the wrong message.

Certainly your loop doesn't work - or at least I have to take your
word for it. That is a far different issue.

Loops do work if you follow standard practices.

The real question is:
"Is a loop my solution?"
and with that comes the $64,000 prize.

In other correspondence you describe noise levels pushing the S-Meter
to S9. If that noise is coming from one direction, a dipole or loop
can solve it. If it is general (meaning that your neighbor's fish
tank heater is bathing you in noise), then you don't stand a chance.

You don't need an antenna, yet. You need to find the source of noise.

Sorry Richard, but if you listen to Antonio, you might learn
something about conservation of energy. He is one of the few
posters who seems to have a grasp of the technical facts that
have, so far, eluded you and other gurus.

I take part of this back. Power indeed can be represented as a vector, not
just scalar.

Piece of cake. The sources are beams of light from Alpha Centauri.
Now tell us exactly how Alpha Centauri adjusts its power output
from 11 light-years away.

Forgot to also mention that, obviously, shutting off one of the two remote transmitters causes no change in the power delivered by the other transmitter.

S meter readings are pretty meaningless, but using the convention of 50uV
for S 9, 6dB/SPoint, ITU-R P.372-8 does indeed suggest median noise at
~S7 for a 2kHz bandwidth and Residential locale.

As to whether your receiver indicates S7 accurately, that is another
matter.

People who brag about S1 noise level on 80m have a lossy antenna and/or
(and) an innaccurate S meter.

Roy Lewallen wrote:
> I see Cecil is still superposing his waves of average power.

That's at least unfair and at most unethical, Roy. I am not superposing power. I am using the accepted irradiance equations from optical physics to predict the energy result of superposing EM waves, something that was being done by physicists before you were born.

> I have an example that's more fun yet.
> Take a 10 volt source ...

It may be more fun but irrelevant. Please explain how the sun can adjust its energy output depending upon what might or might not be happening on earth. If you can do that, I will retract everything I have said about this subject.

You should be able to get it here:

http://thewireman.com/antennap.html

I just use what I can find. Usually some # 14 or #12 insulated stranded
wire. Mostly free from where I work. When some of the older construction
is removed there is lots of wire that would be thrown away that has been in
conduit in the building for 10 to 30 years.

Once it is up in the air there is no best wire (as long as it is copper) as
far as the signal goes. If you could measuer to the tenth of a db, there
may be. The main thing is will it stand up to the weather.

S-9 is 50 uv on this receiver on 40meters - can't be sure its exactly the
same on 80, but the calibration voltage for S9 is very very close on 80.

Well, power is a vector quanity subject to the rules of vector math. But look at it in terms of the energy domain:

The total energy in the system over any time interval is equal to the sum of the each power integrated over each segment of the transmission line during the same time interval.

There will be real power which, when integrated over time on some segments, will be greater than the real power integrated over other segments (the segments are at different locations). But the average power of the entire transmission line (in the closed system), integrated over a given time interval will be equal to the average power of the source integrated over time during the same time interval.

I reinforce what Roy has said with different words: Superposition and linearity are one and the same. If a circuit or process is linear, then superposition gives correct results. If superposition works, then the circuit or process is linear. Power is not a linear process. Power involves multiplication.

When investigating the results of multiple voltage and/or current sources (including E or H from an antenna) all at the same frequency, one performs an addition (vector addition). Then, and only then, one may (note the permissive form) use the resultant voltage or current or impedance (two of the three) to calculate (complex) power. (In the antenna case, recall that Z is near 377 ohms only in the far field.)

Of course it was obvious from the base posting in this thread that the
"waves" must be on a TEM transmission line. But you still haven't
said anything about HOW you launched two distinct waves but got them
to combine into one.

You're working WAY too hard on this one if you have to bring Poynting
vectors into it.

art... if you measured, and have scientifically accurate data showing that a physically and electrically small, directional and rotatable antenna of your
design for 160 m is even 50% as efficient as an unloaded 1/4-wave vertical with a "broadcast-quality" buried radial r-f ground system, please provide same.

A rotatable, wire coat hanger on the top of a tower meets your stated criteria, but certainly is NOT an effective radiator on 160 m.

What, exactly, are you describing, and what is its performance compared to other radiators with known, proven characteristics?

RF

So, the ratio is 1.2.

Two thirds (actually 1/1.2^2) of your total noise is from the receiver internal noise. That is not a good situation, S/N on signals will be degraded by relatively excessive contribution from the receiver, actually caused by inadequate antenna gain.

Expected ambient noise level from a lossless antenna in 2kHz at 3.6MHz should be around -82.9+33dBm or -49.9dBm. The 80m loop gain is about -47dBi, so expected receive level would be -97dBm which is some 40dB above your receiver noise floor.

Things aren't working like they should, so you need to localise the problem.

I have no idea of the sensitivity or bandwidth of your receiver, but a good (not outstanding, just good) (bare) receiver with a noise floor of -130dBm should see a large increase in noise moving from dummy load to the loop. (Ambient at -97dBm would be equivalent to S5 if your S meter was accurate.)

Just for verification, I performed the same test you did, but with a 600mm a side untuned loop and an ICR20 receiver, and I got a 10 fold increase in noise from the loop compared to the dummy load. Your loop is larger and tuned, so it should be a 10dB more sensitive.

BTW, I didn't state it, but those noise measurements MUST be made in SSB mode.

Balham Hill Post Office (14/Nov/2002)

Certainty level: 80%

By mid-November 2002 the persecution had again dwindled, as happens sometimes, when along came this item.
I spent most of my time at home, going occasionally to the shops in Clapham South, or into town to meet people. On this particular
Thursday I only left the house once, for less than fifteen minutes to post a letter (special delivery, because my ordinary and
recorded delivery letters had been disappearing en route for some time - not that anyone would accuse MI5 of such petty harassment).
At the post office counter there was an Asian guy talking into his mobile phone and grinning away. There is a probability that
his comments were directed at me, as I will explain further. The second segment of audio closely follows the first segment.

"you'll do it today? let's meet about 3 o'clock and have some lunch. I got stuff to do and I'll go to the bank,
get this sh.. fucking moving yeah. Even just a little bit do something. He doesn't understand, you know what it is,
I don't want to tell him again cause then he might, he thinks we're having a go at him, I'm not having a go at him,
I'm explain to him"

Explanation: The guy is talking about some bloke who is unnamed, however it might be interpreted as being in code about me.
"I'll go to the bank"... variously interpretable, either literally, or as sounds-like "wank" which has been a consistent
theme in MI5's abuse. "get this shit fucking moving"... abuse... could be interpreted as MI5's criticism of my inertness.
The state spends hundreds of thousands of pounds a year - they want to see some result, not just neutrality and ordinariness.
"he doesn't understand"... MI5 claim I'm stupid... but the numbers and bits of paper prove otherwise, so perhaps what that
is really about is their agents' subconscious perception of themselves.

"having a go at him"... sounds like they're having a go at me, doesn't it? You might take the audio at face value and assume
it's about some other guy, but it's normal MI5 procedure to pretend to be talking about someone else, and make the content of
the message very relevant to me, or their perception of me.

"for some reason it doesn't get into his head, I don't know why... he's lost it completely, hasn't he"

What reason is there for it not getting into his (my) head? Stupidity is implied. Also implied is that it does get into his head;
we're intentionally causing him damage. He's lost it completely... for some time I have suffered from OCD... lost it completely
is the persecutors' observation of my illness, which they see through the surveillance on my home, which they caused.

Hi Tony,

I haven't bothered to wade through ALL the responses so far, but I am left wondering just what you did build. Could you explain it in more detail? Diameter, number of turns, how you're feeding it, how it's "shielded," exactly where the gap is, ... All the details.

A loop can be effective in decreasing noise in two ways. If the noise is electromagnetic radiation it can only work if that radiation is coming from one direction, and in that case, you orient the loop to reject radiation from that direction. You better not want to be receiving a signal from the same direction, of course. The second way it can help is by rejecting locally generated electric field noise--where you are in the near field of the source, and the electric field is considerably stronger in relationship to the magnetic field than it is in electromagnetic radiation. But the electric and magnetic fields fall off with distance rather quickly, so this only works if the noise source is on the order of a wavelength or less away.

In order to build a loop that's effective in not responding to an electric-only field, it must be small compared with a wavelength. I'd think you'd want something around a foot in diameter for 80 meters, possibly slightly larger. You won't pick up much signal, but more importantly, it will be a high Q loop that you need to tune, and the resulting bandwidth will not be great. I have a suspicion that's where your problem lies. Reg Edwards supplied us with a very decent loop analysis program that might give you some insights. Look for rjeloop3.exe under http://www.we0h.us/G4FGQ-index.html.

Cheers,
Tom

Since Energy is the integral of power over time, and since the law of
conservation of energy isn't likely to change soon, it doesn't look like
this agrument is going to get any better for you in the near future either.

I did the measurements in the SSB mode.

This receiver is very quiet with no antenna connected.
When I tune the preselector for a peak in noise the noise jumps up
noticeably.

What about the AGC setting?

My apology. I too-quickly and incorrectly read your "and no the gap is there" as "no gap is there". My statement about your creating a truly shielded loop was wrong. The loop with the gap should work as intended.

"Shielded" loops aren't a folk tale, they work fine. They have a broad pattern with, if constructed properly, narrow and deep nulls. It's a mistaken idea about how they work that's the folk tale.

Nobody has said that power is a linear process.
The equation for adding EM powers has been known
for decades and if it didn't work, it would have
been discarded. As it is, one can find the power
density equation in any appropriate physics textbook.
The method of adding powers associated with two
coherent collinear EM waves is:

Ptotal = P1 + P2 + 2*SQRT(P1*P2)cos(A)

where 'A' is the phase angle between the E-fields
of the two waves.

The waves are launched by the external reflection from a
Z0-match and the internal reflection from the load.

Exactly. Misdirection is the primary tool used by magicians (illusionists) to distract us into thinking something is occurring which really isn't. Its utility hasn't been lost on those wanting to divert our attention from the flaws in their arguments.

Pay no attention to the man behind the curtain. . .

I use a lot of solenoid loops. You should not need a preamp
with a decent size loop using an R4C in most cases.
I'm wondering if you are actually tuning the loop to resonance.
Do you notice a sharp, fairly high Q peak of noise and signals
at the point where you think it is tuned?
There will be no mistake hearing this peak if it's working
correctly.
400 pf seems kind of low to me...
IE: lets take a regular solenoid loop, being calculated by
Reg Edwards loop program rjeloop3.exe..
It's fairly accurate.
I set up a one turn loop using a 20 mm wire, each side
of the loop 5 ft, or 1525mm. I set 1900kc as the
desired frequency, which is the middle of the band.
It shows a stray capacitance of appx 9 pf, and requires
appx 1350 pf to tune to 1900 kc.
See my problem with your meager 400 pf?
Of course, you using coax instead of plain wire may
be effecting the results..
I'm just not sure if you are actually tuned.
I have two solenoid loops that I often use. One is a
16 inch circle, and the other is a diamond loop
44 inches per side.
The 16 inch loop uses appx 12 turns. The larger
loop, 5 turns. I still use fairly large values of caps
to drop down low in frequency. IE: a dual 365pf BC
radio cap, with both gangs tied together is usually
needed to cover the whole BC band.
On my large loop, the various gangs of the cap
add up to a good bit more than 730 pf..
More like 1000+ pf or so.. So I get a wider tuning
range, and can switch gangs out to get small
values for the higher bands.
Anyway, when building small loops, you usually must
build the loop around the cap at hand, rather than

try to match the cap to a set number of wires.
You would think a "planned" loop would work though..
Anyway, the first thing I would need to know is
do you hear a sharp noise peak when "tuned"?
You should. And you really should have enough
signal to not need a preamp in most cases.
As an example, the loss in comparing the 5 ft
per side loop vs a 1/4 wave monopole is appx
-21 db according to the program. "1900 kc"
That should not be enough to kill you on the lower
bands.
I run both of my loops straight to my IC-706mk2g
most of the time, and need no preamp at all on
160m or BC. And I don't have to enable the radio
preamp either.
It's possible you could have a problem with the
preamp. :/
If you want to try a solenoid loop, here is the program.
http://home.comcast.net/~nm5k/Rjeloop3.exe
I put it on my server, as I forgot where the archive
of all his files are..
A simple way to make a PVC frame is here..
http://home.comcast.net/~nm5k/loop5.jpg
The loop you have should work ok once tuned, but
there seems to be a problem of some kind.
Is your feed line ground shield making a connection
to the loop on the other side of the cap from the
center pin connection?
I use separate coupling loops on mine and the coax
feeds that loop. The variable cap is connected in parallel
across the main loop connections.
I get better balance and cleaner nulls if I use a
coupling loop vs feeding directly at the cap/loop
connection. But of course, I'm not using a "shielded"
loop to aid in balance. But in the end, I get just
as clean nulls as the shielded loop.

I know it is popular to make measurements with no antenna connected
(meaning the antenna jack is left o/c). The measurements are meaningless.

Measurements with a matched load are meaningful, the noise output power
of the receiver is due to the equivalent receiver noise power + the noise
in a matched load.

You will also see discussion of whether receiver noise increases or
decreases when a matched load is disconnected... it varies from receiver
to receiver and it highlights the useless nature of the o/c measurment.

> When I tune the preselector for a peak in noise the noise jumps up
> noticeably.
>
> What about the AGC setting?
>

To make a meaningful comparison, the receiver gain must not change
between measurements, so no change in AGC, no change in RF or AF gain,
safest if there is no S meter reading for both measurements.

Turning AGC off doesn't necessarily extend the range of the SSB receiver
where audio output is linearly related to RF input, don't depend on it
unless you have measured its performance.

My recommendation of Copperweld by brand was made only because it's a known quantity. I'm sure there are other brands which are just as good. But I'll bet there are others with a skimpy copper plating, or cladding that might be thin enough to allow current in the steel, particularly on the lower bands.

You need to be more cautious using stranded copper clad steel wire than solid wire. Even though the copper might be equally thick in terms of wire diameter, smaller diameter individual conductor strands mean a thinner coating in absolute terms. The only time I've actually had a problem was with RG-174 sized coax, where the loss was much higher than expected on the lower bands because of the very small center conductor strands, and I think the conductor was genuine Copperweld. But a combination of small strands and less-than-Copperweld thickness might be enough to result in considerable extra loss in some antenna sized wire.
